Thoroughly evaluate the nasal cavity and nose. Determine the adequacy of the reduction procedure. Determine visually whether the nasal bones and the nasal septum are reduced. Consult an Otolaryngologist if the manipulations fail to provide a satisfactory reduction, if the fracture appears too comminuted, or if the nose or septum is too deviated for a closed approach. The patient may require open reduction 2 weeks from the day of the trauma. **Perform a thorough examination to rule out an associated septal hematoma. This must be evacuated and managed to prevent complications.** Refer to

FIGURE 203-15. Intranasal injection of local anesthetic solution: (1) the nasal spine, (2) the nasal tip, (3) the nasal dorsum along the outside of the nasal bones, and (4) the infraorbital nerve.

Chapter 204 regarding the details of managing a nasal septal hematoma. Attempt to suture any nasal septal mucosal tears that exist from the fracture or the reduction procedure using 5-0 plain gut suture. Warn the patient of the potential for a septal perforation that can lead to chronic crusting, bleeding, or an audible whistling. Obtain postreduction photographs of the nose, if possible. Place the prereduction and postreduction photographs in the patient's medical record.

AFTERCARE

Brace the septum for stability with bilateral Silastic splints for 5 to 10 days, although 1 day may be as effective.⁴⁸ This also helps to prevent the formation of a nasal septal hematoma. Doyle or Goldsmith septal splints have lumens that allow the patient to nasally breathe in the postoperative period. These splints must be kept open by the patient applying six drops of hydrogen peroxide to each nostril three times a day while avoiding swallowing this solution. A simpler and more convenient alternative is bilateral anterior nasal packing. The equipment is readily available in every Emergency Department. This is especially useful in cases of epistaxis. Apply bilateral petrolatum-impregnated gauze ribbon, iodinated gauze ribbon, nasal sponges/tampons, or balloon catheters. **Avoid overpacking the nasal cavity as this can splay out the fractured nasal bones.**¹⁰

All patients with nasal packing must be placed on oral antibiotics with gram-positive and gram-negative coverage, such as cefazolin (i.e., Keflex), for the duration of the packing. This will aid in the prevention of a sinusitis or toxic shock syndrome. Leave the nasal packing in place for 1 to 7 days depending upon the amount of manipulation, the amount of bleeding, and Emergency Physician preference. Avoid nasal splinting and packing in patients with nasal fractures requiring a minor degree of manipulation, especially when patients are assessed to have a low probability of follow-up and compliance.

Consider applying an external splint in addition to the internal splint or nasal packing. Some authors do not advocate external splinting and its use is based on Emergency Physician preference. The splint serves to support the healing fracture and to remind the patient to keep their nose protected. Cleanse the skin of the nose and the surrounding area with alcohol. Apply benzoin solution to the nose and surrounding area. Allow the benzoin to dry and become tacky. Apply 1 inch wide paper tape in horizontal strips layered downward from the nasofrontal angle to the tip of the nose. Apply benzoin solution over the tape. Allow the benzoin to dry and become tacky. Apply three to five layers of 2 inch wide orthopedic plaster of Paris over the tape. Alternatively, apply an appropriately sized Denver aluminum, polyvinyl siloxane, or Thermoplast splint

FIGURE 203-16. Closed reduction of a nasal fracture. **A.** Measure the nostril to nasofrontal angle (N-NFA) distance with the Boies elevator or another instrument. **B.** Place the elevator or forceps intranasally just less than the N-NFA distance and elevate the depressed bone. Simultaneously reduce the contralateral nasal bone downward.

FIGURE 203-17. Placement of nasal reduction forceps. Note the rubber tubing over the outer tong to protect the skin.

over the tape (**Figure 203-19**).⁴⁹ Ensure that the foam rubber strut is placed vertically over the midline length of the nose to prevent any skin necrosis. Place tape over the splint to secure it.

Instruct the patient to return to the Emergency Department for excessive bleeding, increased pain, a purulent or foul nasal discharge, or a fever. Prescribe acetaminophen supplemented with narcotic analgesics as needed. Instruct the patient to avoid aspirin-containing products and nonsteroidal anti-inflammatory drugs as they can increase the risk of bleeding. Arrange follow-up with an Otolaryngologist or Plastic Surgeon within 24 to 48 hours to assess the reduction and the need for further management. The use of ice packs several times a day may decrease pain and swelling.

COMPLICATIONS

Pack (or repack) the nasal cavity, after providing adequate local anesthesia, if bleeding occurs. A septal hematoma is likely if a patient complains of persistent or excessive pain, has noticeable nasal widening, or has an ecchymotic septum. This must be evacuated as described in Chapter 204. Infection, cartilage necrosis, and disfiguring nasal dorsal saddling may occur if the septal hematoma

FIGURE 203-18. The Asch forceps to elevate a frontal/inferior force fracture and straighten the associated deviated nasal septum.

FIGURE 203-19. Postreduction Denver splint applied after appropriate taping and midline vertical foam rubber placement.

is not evacuated. A nasal dorsal hematoma can occur as well and must be recognized and evacuated. Cerebrospinal fluid rhinorrhea and visual impairment are rare complications of the nasal manipulation but more likely complications of the original trauma. Cerebrospinal fluid rhinorrhea can be delayed from the initial trauma until the edema has subsided. The reduction may be inadequate and require further closed or open reduction.

The patient may not be satisfied with the results of the reduction, especially if the nasal fracture results from an assault.⁴³ This is more likely to occur in Single Immature Males that are Overtly expectant and Narcissistic, also referred to by the acronym SIMONs, despite an adequate reduction.⁴³ Other studies have shown that overall patient satisfaction did not differ whether reduced under local anesthesia versus in the Operating Room under general anesthesia.^{44,50}

SUMMARY

Nasal fractures may be reduced and repaired in the Emergency Department using a closed technique. Perform the reduction ideally within 3 hours of the injury before significant edema occurs. It is otherwise best to wait until the swelling subsides in approximately 1 week. Repair any nasal septal fractures at the same time as the nasal reduction. Severe fractures sometimes require an open reduction. Photographic and radiographic documentation can be important medicolegally as part of the preoperative evaluation. Drain any septal or nasal dorsal hematomas. Internal and external splinting are useful to help ensure good postoperative healing. Antibiotics are essential if nasal packing is applied.

204

Nasal Septal Hematoma Evacuation

Michael Friedman and Jessica Tang

INTRODUCTION

Soft tissue and bony injuries of the nose are common because the nose is centrally located and the most anteriorly protruding structure of the face.^{1,2} Suspect a nasal septal hematoma, although an uncommon complication of nasal trauma, in any individual who has sustained a nasal injury.^{3,4} All individuals who have sustained nasal trauma must undergo a careful examination of the septum and nasal passages regardless of the mechanism of injury or the findings on external examination.^{3,5,6} A nasal septal hematoma is blood or a clot accumulated between the cartilaginous nasal septum and the overlying nasal mucosa.⁷

Blunt trauma, either intentional or unintentional, is the most common cause of a nasal septal hematoma. Consider a bleeding diathesis if the hematoma develops after a seemingly trivial injury.^{3,8-10} Other etiologies include sports injuries and child abuse.^{8,9} Iatrogenic nasal septal hematomas following nasal septal surgery are probably more common than reported in the literature. Evaluate patients who have had recent nasal surgery and present with complaints of pain and nasal obstruction for a possible nasal septal hematoma.

Nasal septal hematomas are characterized by severe localized nasal pain, tenderness, instability on palpation of the nasal tip, and a cherry-like swelling or bluish discoloration of the nasal mucosa emanating from the septum that obstructs all or a portion of the nasal passage (Figure 204-1).^{1,3,4,11-13} **Septal hematomas can also present bilaterally if a fracture of the nasal cartilage is involved and allows blood to dissect through the fracture. Thus, it is critical that both nares be examined scrupulously.** Evacuation must be performed to prevent complications.^{1,3,8,10,14,15} **Infections can develop as soon as 3 days after injury. A simple incision to allow the clot to drain followed by anterior packing is usually adequate as an initial management.**

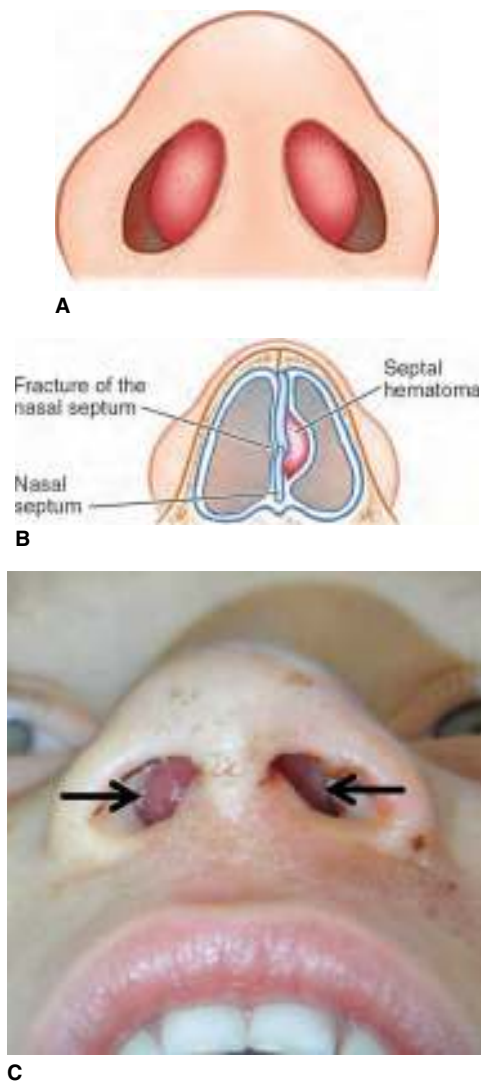

FIGURE 204-1. The nasal septal hematoma. **A.** Bilateral nasal septal hematomas creating a partial obstruction. **B.** Anatomy of a nasal septal hematoma. **C.** Bilateral nasal septal hematomas (arrows). (Photo used with permission from reference 14.)

The most common complication of a nasal septal hematoma or an abscess is cartilage necrosis that results in nasal structural collapse and a saddle nose deformity (Figure 204-2).²

ANATOMY AND PATHOPHYSIOLOGY

The nose is a sensory organ and a respiratory organ. It performs an important function for the entire body by providing physical and immunologic protection from the environment.¹⁶ The nose aids in the formation of basic speech sounds.¹⁶ The supporting structure of the nose consists of bone, cartilage, and connective tissue. The nose, on frontal view, is in the shape of a pyramid, of which approximately the upper two-fifths comprise the bony vault and the lower three-fifths comprise the cartilaginous vault. The upper narrow end joins the forehead at the glabella and is referred to as the root of the nose. The two nares are separated from each other by a skin-cartilage septum known as the columella.^{16,17} The cartilaginous framework of the nose provides its structure and function. The septal cartilage is avascular and receives its blood supply from the adherent mucoperichondrium.

The skin covering the external nose is thin and contains an areolar type of subcutaneous tissue. The skin is loosely attached over

FIGURE 204-2. Artist illustration of the saddle nose deformity.

the upper half. The skin over the lower half of the nose is intimately bound to the lower lateral cartilage and may sometimes be thick, fatty, and contain sebaceous glands.^{9,10}

The precise mechanism for a nasal septal hematoma formation following nasal trauma is not known. Nasal septal hematomas are thought to occur when a mechanical force to the nasal cartilage results in rupture or leakage from the perichondrial blood vessels of the nasal septum. In instances where the nasal cartilage is fractured, blood may dissect through the fracture line and form bilateral septal hematomas. Most nasal septal hematomas are secondary to a fracture or surgery. **They almost always distend the mucoperichondrium on both sides of the nose.** Accumulation of the extravasated blood strips the perichondrium from the cartilage forming a closed space in which the blood accumulates (Figure 204-1). The nasal septal hematoma, when not recognized initially and evacuated promptly, can expand and mechanically obstruct the blood vessels that supply the nasal cartilage.¹⁸ Pressure-induced avascular necrosis of the nasal septal cartilage can develop rapidly because there is no alternative blood supply to the cartilage.^{1,3,4,13} The accumulated blood and necrotic tissue can form a nidus for infection from bacteria that colonize the nasal mucosa.^{1,3,4,13} **Prolonged ischemia can cause septal perforation and irreversible damage if untreated for 3 to 4 days.**

Cartilage necrosis subsequently leads to the saddle nose deformity (Figures 204-2 and 204-3). The term “saddle nose deformity” is a nonspecific description of a nose with a depression over its dorsal surface.¹⁶ The saddle nose deformity is a result of the nasal septal cartilage becoming ischemic from loss of its blood supply, subsequent nasal septal cartilage resorption and collapse, and the lack of support for the nasal bridge. The deformity is the ultimate result of a nasal septal hematoma or abscess not being evacuated. Necrosis with subsequent fibrosis may develop causing a permanent thickening or absorption of the nasal septum with partial obstruction of the nasal airway.^{13,16,19} **Other facial deformities including displacement of the maxilla, retraction of the anterior nasal septum (i.e., columella), widening of the nasal base, and diminished nasal cavity size can result when necrotic tissue is replaced by fibrous tissue with subsequent retraction of scar tissue.**

The sphenopalatine branches of the internal maxillary artery and the ethmoidal arteries from the ophthalmic artery supply the internal nose. The veins terminate in the anterior facial and ophthalmic

FIGURE 204-3. The saddle nose deformity. **A.** A young woman. (Photo courtesy of J. Hilinski, MD.) **B.** A middle-aged man. (Photos courtesy of T. Lampertini, MD, at www.drlampertini.com.)

veins.¹⁷ Venous drainage is clinically important in understanding the complications of a septal abscess. Branches of the trigeminal nerve provide sensory innervation to the nose.^{16,17}

INDICATIONS

Any significant nasal septal hematoma requires evacuation. A nasal septal hematoma may progress to form an abscess with associated complications of avascular necrosis of the nasal septum, meningitis, or cavernous sinus thrombosis in as little as 3 to 4 days.^{13,19} It is not urgent to evacuate a simple nasal septal hematoma in the Emergency Department as complications occur over a period of days. It is essential, however, to identify a nasal septal hematoma so

that a treatment plan is initiated and to rule out a septal abscess that does require immediate evacuation.⁸

CONTRAINDICATIONS

There are no absolute contraindications to the evacuation of a nasal septal hematoma. Address any life-threatening or serious injuries prior to drainage of the nasal septal hematoma. **This procedure requires a cooperative patient to prevent secondary iatrogenic injury.** Any patient who is uncooperative, unable to follow instructions, very young, or who has an altered mental status may require evacuation under procedural sedation (Chapter 159) or general anesthesia.

EQUIPMENT

- Headlight
- Nasal speculum
- Nasal vasoconstrictor (e.g., 2% ephedrine, 0.25% oxymetazoline or phenylephrine)
- Nasal anesthetic (e.g., 4% cocaine, 2% Pontocaine, 4% lidocaine)
- Nasal atomizer device, optional
- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Cotton-tipped applicators
- 1 and 10 mL syringes
- 25 or 27 gauge needle, 1½ inches long
- Local anesthetic solution containing epinephrine, lidocaine, or bupivacaine
- #15 surgical blade on a handle
- Frazier suction catheter
- Suction source and tubing
- Nasal speculum
- Bayonet forceps
- Nasal tampon or sponge
- Iodoform gauze

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Obtain a signed consent for the procedure. **Aseptic technique should be followed and maintained throughout the procedure.** The procedure is considered clean, but not sterile, as the nasal mucosa can never be sterilized. **It is crucial that the instruments used are sterile.**

Administer anesthesia for the evacuation of a nasal septal hematoma by one of two routes: topical application with supplemental infiltration or a regional block. Some authors recommend using both techniques. Most nasal septal hematomas can be adequately evacuated with topical anesthesia supplemented by local infiltration.¹³ Dampen the swabs of four cotton-tipped applicators with either a solution of 2% Pontocaine with ephedrine or cocaine. Insert a nasal speculum to expose one nostril. Gently insert the applicator beneath the roof of the nose so that it reaches the branches of the anterior ethmoidal nerve (**Figure 204-4**). Pause until some vasoconstriction and anesthesia takes place if it meets resistance on insertion and then advance the applicator further (**Figure 204-4**). Pass an applicator into the nasal fossa and move it from the floor of the nasal vestibule, across the midportion of the inferior turbinate, and reaching the posterior aspect of the middle turbinate in the region of the sphenopalatine foramen.²⁰ Infiltrate a maximum of 0.5 mL of local anesthetic solution containing epinephrine, if additional anesthesia is desired, through the mucoperichondrium and circumferentially around the hematoma.

An atomizer or nasal spray bottle can provide an alternative and commonly used method for nasal septal anesthesia (Chapter 205 and **Table 205-1**). Although an actual atomizer is not often available in the Emergency Department, its use is less painful to the patient than the application of cotton-tipped applicators into the nasal cavity. Alternatives to an atomizer are devices that attach to a syringe to atomize the contents or use of a commercially available nasal spray container after emptying its contents. Mix equal amounts of 2% Pontocaine or 4% lidocaine with ephedrine and place this in the atomizer or nasal spray bottle. Insert the nasal speculum to gain access to the

FIGURE 204-4. Cotton swab technique for nasal septal anesthesia.

entire nasal cavity. Open the nasal speculum vertically to expose as much of the nasal septum as possible. Insert the atomizer or nasal spray bottle into the nostril. Instill two puffs of solution into the nostril. Allow 5 to 10 minutes for the anesthetic to take effect. Infiltrate a maximum of 0.5 mL of local anesthetic solution containing epinephrine, if additional anesthesia is desired, through the mucoperichondrium and circumferentially around the hematoma.

Reconfirm the presence of a septal hematoma.⁵ Compress the area with a cotton-tipped applicator. The bulge from the hematoma is compressible with the applicator. **A nasal septal hematoma will not shrink with the application of a topical vasoconstrictor.**^{3,9,21}

TECHNIQUES

ASPIRATION

Some feel that simple aspiration with an 18 gauge needle may be adequate for a small and early hematoma. Most patients require a more extensive evacuation as clotted blood cannot be removed with aspiration. Needle aspiration is generally not effective since blood clots form within minutes and remain in clotted form for days. Simple aspiration may, however, be used to distinguish a septal hematoma from an abscess.^{9,13,19}

Insert the nasal speculum. Open the nasal speculum vertically so that the nasal septum is maximally visible. Instruct an assistant to hold the nasal speculum in position and open. This will allow the Emergency Physician to have both hands free to perform the procedure. Insert an 18 gauge needle attached to a 10 mL syringe into the nasal septal hematoma. Aspirate the contents of the hematoma. No additional procedure is necessary if the hematoma can be completely evacuated by aspiration. Simple clinical assessment of the septum is the guide to determine if the hematoma has been evacuated. Apply a nasal pack as described below.

INCISION AND DRAINAGE

The incision and drainage technique is the primary procedure to drain a nasal septal hematoma.^{11,21-23} Cleanse the skin surrounding the nares of any dirt and debris. Apply an alcohol swab, povidone iodine, or chlorhexidine to the area and allow it to dry. Insert the nasal speculum. Open the nasal speculum vertically so that the nasal septum is maximally visible. Instruct an assistant to hold the nasal speculum

FIGURE 204-5. Nasal septal hematoma with markings for a vertical incision through the mucoperichondrium.

in position and open. This will allow the Emergency Physician to have both hands free to perform the procedure. Make a 1.0 to 2.0 cm long vertical incision with a #15 scalpel blade in the septal mucoperichondrium overlying the hematoma (**Figure 204-5**). **Be cautious to not cut into the cartilaginous septum.** The length of the incision depends upon the size of the nasal septal hematoma. Some authors prefer to use an L-shaped incision in the mucoperichondrium.²⁴⁻²⁸ These authors feel that this incision allows the mucoperichondrium to reposition flat against the cartilaginous septum. The choice of incision type is left to the preference of the Emergency Physician.

Use the Frazier suction catheter to gently evacuate any clot or necrotic debris from the hematoma cavity. Clots are difficult to evaluate by suction and may require mechanical removal. Always send a sample of the fluid or hematoma to the laboratory for Gram's stain, anaerobic cultures, and aerobic cultures.^{3,13,19} Apply topical antibiotic ointment over the incision, a wick, and nasal packing as described below.

A bilateral septal hematoma can almost always be evacuated from one side. Apply gentle pressure to the contralateral hematoma to express it out of the incision. Make a second vertical incision contralaterally and anterior or posterior to the first incision. **The staggering of the incisions prevents septal perforation if complete evacuation is not achieved unilaterally.**

WICK INSERTION

Insert a wick of 1/8 inch iodoform gauze through the incision (**Figure 204-6**). Allow 1 inch of the wick to extend into the nasal cavity for easy removal. **Be careful to ensure that the wick is flat between the mucoperichondrium and the cartilaginous septum. Do not pack the cavity with the wick.** Some authors recommend inserting a Penrose drain, or a piece of one, instead of the iodoform gauze.⁹ This has not been found to be beneficial when compared to iodoform gauze.⁹ The Penrose drain can be a substitute if iodoform gauze is not available or the patient is allergic to iodine.

NASAL PACKING

Apply bilateral nasal packs following the successful drainage of a septal hematoma (Chapter 205). Packing inhibits the reaccumulation of the hematoma or serous fluid and prevents the severe complications associated with a septal hematoma. The use of commercially available nasal packing devices (e.g., nasal tampons or sponges) provides adequate protection against reaccumulation.²¹ Patients report these

FIGURE 204-6. Iodoform gauze is placed between the separated mucoperichondrium and the cartilaginous septum.

to be significantly more comfortable than traditional gauze packing. In addition, their ease of insertion when compared to gauze packing has made these commercial nasal packing devices very popular.

Place the patient's head in the sniffing position. Coat a nasal tampon with a water-soluble antibiotic ointment. Insert the nasal speculum to obtain adequate visualization of the nasal septum. Grasp the nasal tampon with a bayonet forceps. Introduce the forceps with the nasal tampon in a horizontal position through the speculum. **Be careful to not tear the incision in the mucoperichondrium open or to dislodge the wick.** Place the nasal tampon on the floor of the nasal cavity and against the nasal septum.¹⁹ Withdraw the bayonet forceps and the nasal speculum. Repeat the nasal packing procedure on the contralateral side. **Both nasal cavities must be packed to maintain the septum in the midline, prevent bowing of the septum into the contralateral nasal cavity, and prevent the reaccumulation of the hematoma.**

PEDIATRIC CONSIDERATIONS

Nasal septal hematomas can occur at any age.²⁹ The diagnosis and treatment are the same for adult and pediatric patients.^{5,29} Perform any treatment for children under procedural sedation in the Emergency Department or general anesthesia in the Operating Room.¹⁴ **It is crucial to sufficiently inspect the intranasal cavity of children with good lighting because septal injury may still occur in the absence of external physical exam findings. The injury may further evolve over 24 to 72 hours following the initial injury. Periodic examinations for at least 12 to 18 months after injury should be performed to monitor for any cosmetic deformities.**

AFTERCARE

Proper follow-up is vital to prevent any infectious process or cosmetic deformity. All patients must be reevaluated within 24 hours with an Otolaryngologist to prevent complications following the evacuation of the hematoma.^{3,10,19} The patient should follow up again in 48 hours for removal of the nasal packs. The drain can be removed at this follow-up if there is no further blood draining or hematoma formation.¹¹ Prescribe acetaminophen and narcotic analgesics for pain control. Prescribe broad-spectrum antibiotics, specifically those with staphylococcal coverage, as prophylaxis against infection and the development of a septal abscess.⁹ Draining a septal hematoma can convert a closed fracture into an open fracture. Instruct the patient to avoid

nonsteroidal anti-inflammatory drugs (NSAIDs) as they increase the risk of bleeding. Provide all patients with proper discharge instructions. The patient should return to the Emergency Department immediately if they experience increased pain, bleeding, or a fever.

COMPLICATIONS

The most common complication of a nasal septal abscess is cartilage necrosis that results in nasal structural collapse and a saddle nose deformity (**Figure 204-2**).² The most common acute complication of a nasal septal hematoma is an abscess or cosmetic deformity. Complications are primarily related to incomplete evacuation or reaccumulation of the hematoma. This may be avoided by adequate removal of the hematoma with suction, placement of an iodoform gauze wick, and bilateral nasal packing.

Distinguishing an uncomplicated nasal septal hematoma from one that has become infected is difficult. This is particularly true if there has been several days of delay in seeking medical attention following the injury.³ Nasal septal abscesses are a rare complication of nasal septal hematomas that occur following nasal trauma. **Septal abscesses can be distinguished from an otherwise uncomplicated hematoma in that they are generally larger, more painful, and inflamed, and inflammatory exudates may be present on the overlying mucosa.**³ It is important to recognize septal abscesses as they may result in ascending infections including meningitis and cavernous sinus thrombosis.^{18,19} *Staphylococcus aureus* is the primary pathogen isolated from most reported cases regardless of patient age. Prescribe appropriate prophylactic antibiotics.^{3,8,9}

Many patients cannot tolerate complete hematoma evacuation under local anesthesia. Consult an Otolaryngologist and schedule the patient for evacuation under anesthesia within 24 hours when complete evacuation is not performed. Early and/or appropriate treatment may not prevent complications if the nasal septal cartilage is already ischemic at the time of the procedure.

Other complications of nasal septal hematoma drainage are rare and include nasal bleeding, inadequate evacuation, and septal perforation. Nasal bleeding can usually be controlled with the prescribed packing. Incomplete removal of the hematoma is not a serious problem if identified. A nasal septal hematoma may reoccur if the incision is made on opposite sides of the septum. **Limit the incision to one side if possible. The second incision, if required, on the contralateral side must not oppose the first incision.**

SUMMARY

A nasal septal hematoma is a rare but potentially serious complication of nasal trauma. Proper management consists of early recognition, prompt evacuation, wick insertion, and bilateral nasal cavity packing. Administration of antimicrobial therapy is necessary to prevent or treat a secondary nasal abscess. Follow-up with an Otolaryngologist is required within 24 hours of the procedure to evaluate for the reaccumulation of the hematoma and/or an abscess. These patients require continual follow-up until the nasal septum is healed.

Epistaxis Management

Steven Lai and Matthew Waxman

INTRODUCTION

Epistaxis is an extremely common condition in the United States with an incidence estimated at 10 per 10,000 people per year and a lifetime incidence of approximately 60%.¹ It is a common reason for patient visits to the Emergency Department. Epistaxis has a bimodal age distribution with an early peak in those less than 10 years of age.² The frequency of epistaxis decreases in the teens

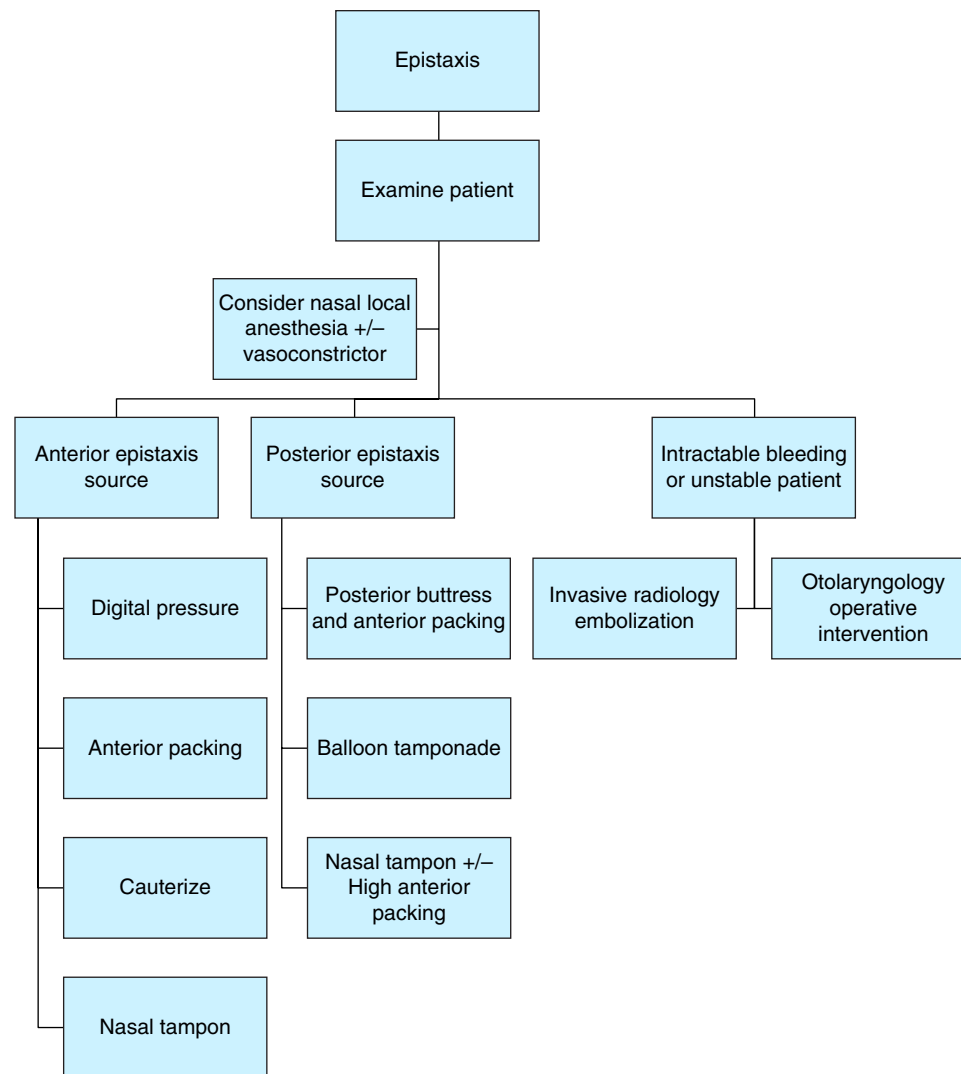

FIGURE 205-1. Methods to control epistaxis.

followed by a progressive increase after 20 years of age with the highest frequency in the elderly.² Epistaxis is usually the result of intranasal trauma. It may be the initial sign of a more serious underlying systemic illness.³ Epistaxis is often self-limited and can be managed conservatively.⁴ Epistaxis can also manifest as a profuse spontaneous hemorrhage that is extremely difficult to control and can result in aspiration, hypotension, cardiovascular collapse, syncope, and airway compromise.

The proper management of epistaxis and the prevention of adverse consequences depend on a timely and thorough evaluation of the patient, appropriate intervention, and expeditious intervention. The Emergency Physician must be familiar with a variety of techniques to control intranasal hemorrhage (Figure 205-1).⁵⁻⁸

ANATOMY AND PATHOPHYSIOLOGY

An understanding of the vascular anatomy supplying the nasal cavity is essential to the efficient and timely control of epistaxis. The blood supply to the sinonasal cavity arises from branches of the internal and external carotid arteries (Figure 205-2). The sphenopalatine artery is the primary blood supply to the sinonasal cavities. The sphenopalatine artery arises from the terminal branches

of the internal maxillary artery which is a branch of the external carotid system. The anterior and posterior ethmoid arteries, the terminal branches of the internal carotid system, supply blood to the superior straits of the nose. The superior labial branch of the facial artery supplies the anterior nasal cavity and anastomoses with branches from the anterior ethmoid artery and the sphenopalatine artery in Little's area of the anterior and inferior nasal septum known as Kiesselbach's plexus (Figure 205-3). It has been estimated that 90% of all nasal bleeding occurs anteriorly in Kiesselbach's plexus.⁹ This is particularly true for children and young adults. Older adults have a higher incidence of bleeding from the posterior nasal cavity which receives its blood supply from branches of the sphenopalatine and posterior ethmoidal arteries. It is in Woodruff's area located at the posterior end of the inferior turbinate. Atherosclerosis and use of anticoagulants are often causes of epistaxis in the elderly.⁹

Epistaxis may result from a combination of local and systemic factors that damage the delicate mucosal lining of the nasal cavity and expose the underlying vasculature.¹⁰ The most common cause of epistaxis is accidental or self-inflicted trauma from digital manipulation of the nasal mucosa (i.e., nose picking). This eventually heals and crusts over but is subject to repeated irritation and bleeding when the patient sneezes or blows their nose. The anterior source of

FIGURE 205-2. The blood supply of the nasal cavity arises from the internal and external carotid artery systems.

this bleeding makes it very easy to treat. High-velocity trauma to the midface and skull base may manifest as a severe or life-threatening hemorrhage that may be extremely difficult to control.

Local inflammatory reactions due to acute upper respiratory infections, allergic rhinitis, and chronic sinusitis may cause epistaxis.¹¹

FIGURE 205-3. Arterial supply to the nasal septum and Kiesselbach's plexus.

The nasal mucosa becomes inflamed, hypervascular, and is easily disrupted with forceful nose blowing. The presence of an intranasal foreign body may irritate the nasal mucosa and form granulation tissue that is prone to bleeding. This should be expected if the bleeding occurs unilaterally and is associated with nasal obstruction and foul rhinorrhea. Illicit intranasal drug insufflation with cocaine or methamphetamine can result in epistaxis due to local trauma, inflammation, or vasoactive effects from these substances.¹²

Epistaxis may be attributed to a nasal septal deformity.¹³ The deflected nasal septum creates turbulent airflow that desiccates the mucosa and leads to crusting and bleeding. Epistaxis attributed to nasal septal deviation presents just posterior to the deflection and may be difficult to control. Nasal septal perforations bleed frequently and easily from mucosal irritation and granulation tissue.

Postoperative bleeding may be encountered from sinonasal surgery (e.g., septoplasty, rhinoplasty, turbinectomy, and endoscopic sinus surgery). Blood-tinged nasal secretions are to be expected for the first 2 weeks after surgery. Severe epistaxis may occur during the first postoperative week with an estimated incidence ranging from 0.9% to 8.9%.¹⁴ The bleeding is usually posterior and brisk and may be difficult to control. Consult the Otolaryngologist who performed the procedure in all cases of postoperative bleeding.

Nasal bleeding may be the first sign of a sinonasal neoplasm. The bleeding is usually intermittent and often accompanied by nasal obstruction and pain. **Severe bleeding is unusual.** An exception occurs with juvenile nasal angiofibromas which have a higher incidence in adolescent males.

Patients without identifiable local causes for epistaxis most likely suffer from an underlying systemic process.³ Congestive heart failure

raises the venous pressure in nasal venules and makes them more prone to bleeding.³ Consider the possibility of a defect in the coagulation cascade. Hypertension is often cited as a risk factor for epistaxis. Studies have been unable to demonstrate a significant difference in the prevalence of epistaxis in patients with hypertension versus patients without hypertension.^{15,16} Nonsteroidal anti-inflammatory drugs and aspirin-containing products have been associated with epistaxis.^{17,18} Osler-Weber-Rendu disease or hereditary hemorrhagic telangiectasia is an autosomal dominant inherited condition in which the blood vessel walls lack contractile elements.¹⁹ Prolonged heavy bleeding occurs from relatively minor insults as the vessels are unable to contract and allow clotting to take place. The patient's coagulation profile is normal and the diagnosis is made by the family history. Other systemic etiologies for epistaxis include alcoholism, blood dyscrasias, liver disease, malnutrition, and pregnancy. Routine laboratory studies are not needed unless the patient is symptomatic for blood loss or has indications of an underlying bleeding disorder.²⁰

INDICATIONS

A patient with epistaxis must be evaluated immediately. All patients with epistaxis require a thorough examination to identify the source and control the bleeding (Figure 205-1). Epistaxis that has resolved still requires evaluation and potential management to prevent rebleeding.

CONTRAINDICATIONS

There are no absolute contraindications to the management of epistaxis. Disrupted anatomy, significant facial injury, or nasal hematomas may be relative contraindications to nasal packing. **Manage any unstable vital signs, impending airway compromise, life-threatening or limb-threatening injuries, or any complications related to blood loss (e.g., hypotension, chest pain, syncope) before managing the epistaxis.** Apply a nose clip (Figure 205-4), nasal sponge, or nasal tampon to control the bleeding in the interim. A thorough examination and more definitive means of control can be performed after the patient has been stabilized.

EQUIPMENT

- Nose clip
- Headlight or overhead light source
- Yankauer suction catheter
- Frazier suction catheters, #5 and #7
- Nasal speculum, short and medium lengths
- Bayonet forceps
- Kidney basin
- Tongue depressor
- Gown, gloves, face mask with an eye shield or goggles
- Cotton balls
- Topical anesthetics and vasoconstrictors
- Silver nitrate applicator sticks
- Petroleum (e.g., Vaseline) impregnated gauze ribbon, 0.5 inches wide
- Nasal tampons, various lengths
- Nasal balloons (e.g., anterior, posterior, anterior and posterior)
- 14 French Foley catheter with a 30 mL balloon
- Umbilical clamp
- Gelfoam
- 4×4 gauze squares
- Surgicel
- ENTaxis nasal packing

TABLE 205-1 Atomizer Devices Available		
Name	Manufacturer	Comments
DeVilbiss Model 15 Medical Atomizer	DeVilbiss Healthcare	Disposable and reusable versions Adjustable tip
Enk Fiberoptic Atomizer Kit	Cook Medical	Pressure-resistant oxygen tubing Atomizes through fiberoptic bronchoscope working channel
EZ-Spray	Alcove Medical	Disposable Trigger valve system
LMA MADdy Pediatric Mucosal Atomizer Device	Teleflex	Disposable single use Comes in various colors and shapes Child friendly Attaches to standard syringe 11.4 cm long
LMA Bottle MADomizer Atomizer	Teleflex	Disposable single-use tips Reusable bottle 10 cm long
LMA MADgic Laryngo-Tracheal Atomizer	Teleflex	Disposable single use Attaches to standard syringe Flexible tube 21.6 cm long
LMA MAD Nasal-Intranasal Mucosal Atomizer Device	Teleflex	Disposable single use Attaches to standard syringe

- 3 inch long dental rolls or tonsil packs or 3×36 inch Vaseline gauze
- Umbilical tape or 0 silk suture
- Red rubber catheters
- Lubricant

The list of equipment required to manage a patient with epistaxis is quite long. Most Emergency Departments keep all the required equipment in a rolling cart or tackle box except the medications. This system allows for more efficient stocking and restocking. It is more efficient to have all the required equipment readily available in one convenient and portable location. Single patient use and disposable nosebleed trays are commercially available (Figure 205-5). They contain some of the most used instruments that are disposable but lack the medications and other supplies. Become familiar with your institutions kit in advance of its need.

Atomizer devices are usually not available in the Emergency Department. Many devices are available commercially, are disposable, and are single patient use (Figure 205-6 and Table 205-1). A popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

PATIENT PREPARATION

Treatment of any patient with epistaxis should start with ensuring a secure airway and hemodynamic stability. Resuscitative efforts should take initial priority over stopping epistaxis if the patient is unstable. Severe epistaxis may obstruct visualization of the airway and make direct laryngoscopy difficult. Fiberoptic airway devices should be available to assist with intubation in anticipation of a difficult airway.

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. Some Emergency Physicians just note a verbal consent in the medical record. Ensure that the patient has a thorough understanding of the postprocedural care instructions and follow-up requirements after the epistaxis has resolved.

Position the patient sitting in an upright multipositional procedure chair. Alternatively, place the patient sitting upright on a gurney with the back elevated. Prepare the wall suction unit to make sure

that it is working. Apply suction tubing and a Frazier suction catheter to the suction source. Don protective equipment (e.g., gowns, gloves, and protective eyewear) to prevent body fluid exposure.

The importance of good lighting cannot be overemphasized. Don a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. A headlamp is preferred as the overhead light often hits the examiner in the head, casts shadows, and is too bright for the patient's eyes. It is also difficult to position properly as both hands must be used for the procedure.

Instruct the patient to blow their nose firmly one nostril at a time to evacuate the nasal cavities before the examination. This allows the anterior nasal septum, Kiesselbach's plexus, the nasal vestibule, the inferior turbinate, and the floor of the nasal cavity to be examined. Inspect the posterior oropharynx for active bleeding using a tongue depressor. Insert a short nasal speculum (**Figure 205-7**) to evaluate each side of the anterior nasal cavity. Open the speculum vertically. Suction out any blood and blood clots with the Frazier suction catheter. Consider a posterior source of epistaxis if unable to identify a

FIGURE 205-7. The Bionix disposable nasal speculum. **A.** The speculum. **B.** Using the nasal speculum. (Courtesy of Bionix, Toledo, OH.)

source of bleeding. It is sometimes difficult to determine from which side the bleeding is originating. A patient will occasionally present with bilateral epistaxis. Ask the patient which side started bleeding first. This is usually the side where the source of bleeding can be found.

Vasoconstrict and anesthetize the nasal mucosa (**Table 205-2**).²¹ Decongest the nasal mucosa with an aerosolized agent (e.g., topical oxymetazoline or Afrin). Use an atomizer (**Figure 205-6**) if available. Put oxymetazoline diluted in saline in a syringe. Attach an atomizer. Give the patient a tissue to control any drips from their

nose. Instruct the patient to sniff in deeply after the spray is applied. Put the atomizer tip in the patient's nostril and briskly depress the syringe plunger (**Figure 205-8**). Allow 3 to 5 minutes for the vasoconstriction to occur. The use of oxymetazoline to vasoconstrict the nasal mucosa may stop the epistaxis and avoid nasal packing.²² A small retrospective study demonstrated that 65% of Emergency Department patients with epistaxis were successfully treated with oxymetazoline and continuous pressure.²³ Next apply a topical anesthetic spray to the nasal passageway. Put 4 mL of 4% lidocaine in a syringe. Attach an atomizer. Give the patient a tissue to control any drips from their nose. Instruct the patient to sniff in deeply after the spray is applied. Put the atomizer tip in the patient's nostril and briskly depress the syringe plunger. Consider spraying the back of their oropharynx followed by the patient spitting it out. Spraying achieves excellent vasoconstriction and anesthesia as the agents diffuse through the entire nasal cavity and pharynx.

Alternatively, it is possible to anesthetize and vasoconstrict the nasal mucosa in one step by using cocaine or a combination of an anesthetic and vasoconstrictor agent (**Table 205-2**). Place cotton pledgets soaked with cocaine hydrochloride (i.e., 4% or 10% solutions) or LET (i.e., lidocaine 4%, epinephrine 0.1%, and tetracaine 0.4%) into the nasal cavity for 5 to 10 minutes to achieve anesthesia and vasoconstriction (**Figure 203-13**). Direct the pledgets along the floor of the nose, against the nasal septum, and toward the superior straits of the nose. Monitor the patient's vital signs when vasoconstrictors are applied.

There are numerous techniques to manage epistaxis (**Figure 205-1**). These include the use of absorbable packs, electrocautery, Foley

catheters, gauze rolls, intranasal balloon catheters, petrolatum-impregnated ribbon gauze, nasal tampons or sponges, and silver nitrate. The technique and material of choice depend upon the location of the bleeding (i.e., anterior versus posterior) and Emergency Physician preference. Different techniques and equipment are required to control anterior versus posterior bleeding.

RADIOLOGIC STUDIES

Routine imaging is not indicated for the evaluation and management of epistaxis in the absence of trauma. A study looking at the utility of computed tomography (CT) scanning in a pediatric population with epistaxis found that 79% of the studies demonstrated some abnormality but none of the patients were found to have a neoplasm.²⁴ Obtain CT imaging of the paranasal sinuses and facial bones when there is a history of facial trauma or when there is a high index of suspicion for a neoplasm.

ANTERIOR EPISTAXIS MANAGEMENT TECHNIQUES

Anterior nasal packing is required when local measures fail to control epistaxis. This may be due in part to anterior or structural problems in which the bleeding source cannot be identified. It may be due to heavy or profuse bleeding. **Nasal packing is effective by providing mechanical pressure and tamponades the bleeding site.**²⁵ **Nasal packing is an uncomfortable procedure. The previously described steps for applying topical anesthesia should be undertaken.**

ABSORBABLE PACKING

Diffuse bleeding is frequently encountered in patients with coagulopathies and blood dyscrasias. The trauma of inserting the nasal packing (e.g., a tampon or petrolatum gauze) can lead to more serious bleeding. A Gelfoam sponge or oxidized cellulose (i.e., Surgicel) is often effective in stopping epistaxis. These substances provide adequate pressure and hemostasis without extreme trauma to the nasal mucosa. This packing does not need to be removed and will slowly dissolve with the use of a topical saline spray which may be started within 24 hours of the packing being placed.

The two most commonly used absorbable dressings are Gelfoam and Surgicel. Gelfoam is an absorbable gelatin sponge that is readily available and inexpensive. It forms a scaffold for the formation of a blood clot. Surgicel is composed of oxidized and regenerated cellulose. It promotes coagulation better than Gelfoam. Surgicel may result in delayed healing and its use should be reserved for persistent bleeding or when Gelfoam is not available.

Absorbable packs may be used for primary and secondary hemostasis. Apply a piece of Gelfoam or Surgicel directly over the site of discrete bleeding or diffuse oozing. The material may be used for secondary hemostasis via placement over an area that has clotted and stopped bleeding. This can serve as a "Band-Aid" to help prevent premature clot dislodgement and rebleeding. These packs can be placed over areas that have been chemically or electrically cauterized. An absorbable pack can be placed prior to packing the nasal cavity with a sponge/tampon or gauze. The absorbable pack will prevent the clot from becoming dislodged when the sponge/tampon or gauze is removed.

Insert the nasal speculum and identify the scabbed or bleeding site. Apply a piece of Gelfoam or Surgicel over the site. Allow a clot to form onto the absorbable packing. The nasal cavity may then be packed with a sponge/tampon, petrolatum gauze, or a balloon catheter if the Emergency Physician chooses to do so in the clinical setting. Packing with absorbable materials tends to be easy to do and comfortable for the patient as the material conforms to the patient's nasal contours.

Two additional absorbable dressings are topical thrombin and collagen. They are expensive, are not usually available in the Emergency Department, and should be limited to circumstances where other hemostatic methods have failed. Topical thrombin is derived from bovine thrombin. Place a piece of Gelfoam saturated with thrombin over the bleeding site. Thrombin converts fibrinogen to fibrin and bypasses the coagulation cascade to form a clot. Collagen is available in multiple forms from a variety of sources. It promotes platelet aggregation and forms a scaffold for the formation of a clot. Cover the bleeding site with collagen followed by a piece of Gelfoam.

CHEMICAL CAUTERIZATION

The most common location of bleeding is within the anterior nasal cavity and on the anterior nasal septum. Sometimes no active bleeding is found at the time of evaluation. Suctioning of the nasal cavity will remove clots and may allow the site to bleed and be visualized. A scabbed excoriation or an exposed blood vessel may be found along the nasal septum. Chemical cauterization of these areas can be achieved using silver nitrate applicators.²⁶

Insert the nasal speculum and identify the scabbed site or the exposed vessel. Apply silver nitrate under direct visualization by rolling the applicator on the area immediately surrounding the scab or blood vessel (**Figure 205-9**). Apply the silver nitrate for 3 to 10 seconds. **Do not apply the applicator in any one spot for more than 10 seconds. This may cause damage and mucosal necrosis to the underlying cartilaginous septum. Do not apply the silver nitrate excessively or in the same spot on both sides of the septum. This may result in a septal perforation.** Apply a topical antibiotic ointment to the area and consider placing a piece of Gelfoam or Surgicel over the site to help stabilize the clot.

A relatively dry field is required to use the silver nitrate applicator. Moderate to severe bleeding results in the silver nitrate

coagulating the blood. This prevents contact with the mucosal tissue and bleeding will continue. Attempt to simultaneously suction the blood while using the silver nitrate applicator. Unfortunately, the suction often pulls off the coagulum and the bleeding continues. A final technique is to apply the silver nitrate centripetally around the bleeding site. This will cauterize the feeder vessels and may stop the bleeding. **Do not cauterize an area over 0.75 cm in diameter. This can result in damage to the underlying cartilaginous septum.** Pack the nasal cavity with a sponge/tampon, petrolatum gauze, or a balloon catheter if these techniques fail.

ELECTRICAL CAUTERIZATION

Electrocautery can effectively control bleeding if the site is identified. **This technique is reserved for the experienced Otolaryngologist.** An electrocautery device should be available for use by the Otolaryngologist. It can cause significant damage to the mucosa and cartilage in inexperienced hands. The technique of electrocautery is not discussed for these reasons.

RIBBON GAUZE PACKING

The traditional technique of anterior nasal packing consists of using 0.5 inch wide petrolatum-impregnated gauze ribbon (**Figure 205-10**). This technique is extremely effective but not often used as it is cumbersome, time-consuming, and simpler methods now exist (e.g., silver nitrate cautery, sponges, tampons, and balloon catheters).

Insert a nasal speculum. Grasp one end of the petrolatum gauze with a bayonet forceps. Insert the petrolatum gauze into the nasal cavity and along the nasal floor (**Figure 205-10A**). Tightly pack the nasal cavity in a layered fashion from bottom to top, extending as far back as possible toward the choanal arch (**Figure 205-10B**).

FIGURE 205-9. Using silver nitrate for chemical coagulation of epistaxis. (Courtesy of www.intranasal.net.)

FIGURE 205-10. Anterior nasal packing using petrolatum (e.g., Vaseline) impregnated gauze ribbon. **A.** Insert a nasal speculum and begin packing inferiorly to superiorly. **B.** The gauze-packed anterior nasal cavity.

Be careful to avoid injuring the mucosa overlying the septum and the turbinates. Cut the petrolatum gauze so that it protrudes approximately 2 cm from the nostril. Tape this loose end to the patient's cheek so that it does not accidentally pull the packing out. The packing is later removed by gently pulling on this free end of gauze ribbon protruding from the nostril.

The pressure of one-sided anterior nasal packing can sometimes bow the septum contralaterally allowing the packing to "loosen" and the bleeding to restart. Consider packing the contralateral anterior nasal cavity to maintain the septum in the midline and exert pressure on the bleeding site.

EXPANDABLE NASAL SPONGES/TAMPONS

One of the easiest, quickest, and most effective techniques to control anterior epistaxis is to insert an expandable sponge or tampon (e.g., Rhino Rocket or Merocel packing). These packs are particularly useful when the bleeding is diffuse, a specific site cannot be clearly identified, or the bleeding is heavy. The packs come in various sizes (e.g., 4.5, 6, 8, and 10 cm), shapes, and styles (Figure 205-11). Initially quite rigid, they soften and expand with the absorption of saline or surrounding blood. A 4.5 or 6 cm sponge is generally adequate for anterior epistaxis.

Prepare the sponge/tampon. Cut the string from the sponge/tampon as it is not necessary to remove the packing. The sponge/tampon is barely visible when properly inserted. The string hanging from the nostril can be irritating to the patient and is not cosmetically appealing. Lightly coat two-thirds of the sponge/tampon with a non-water-soluble lubricant (e.g., Vaseline) or antibiotic ointment (e.g., Neosporin). This will prevent premature expansion of the tampon from a water-soluble lubricant or antibiotic ointment, nasal secretions, or blood.

Insert and open the nasal speculum within the affected nasal cavity. Grasp the unlubricated end of the sponge/tampon with a bayonet forceps or the dominant thumb and index finger. Insert and advance the sponge/tampon just lateral to the nasal septum, in a vertical position, with the length of the pack directed along the floor of the nose (Figure 205-12A). Advance the sponge/tampon until it is completely within the nasal cavity. The sponge/tampon will expand from the blood and secretions within the nasal cavity (Figure 205-12B). Slowly drip 1 to 3 mL of tap water or saline onto the unlubricated tip of the sponge/tampon to help it expand more rapidly.

FIGURE 205-11. Examples of some of the various sizes, shapes, and styles of nasal sponges/tampons.

FIGURE 205-12. The expandable nasal sponge/tampon. **A.** Insertion along the floor of the nasal cavity. **B.** The expanded state.

Inspect the oropharynx for bleeding. Persistent bleeding may be due to the septum bowing contralaterally. Pack the contralateral anterior nasal cavity with a sponge/tampon of equal length and size. Observe the patient for continued bleeding anteriorly or posteriorly. Continued bleeding requires removal of the sponge/tampon from the bleeding nasal cavity and insertion of a larger one, two small ones, or Vaseline gauze packing.

Keep several helpful hints in mind when using the nasal sponges/tampons. Trim long sponges/tampons to 5 to 6 cm in length. The extra length is not required for anterior epistaxis, is uncomfortable for the patient, and is more difficult to remove. The Rhino Rocket is a sponge/tampon within a plastic syringe-like device. Consider removing the sponge/tampon from the syringe-like device before inserting it. The device can generate significant force and result in mucosal tears, septal injuries, and turbinate injuries. Insert and advance the sponge/tampon rapidly to prevent premature expansion. There is no advantage to using a non-water-soluble antibiotic ointment versus a lubricant. The antibiotic ointment is more expensive and its antibacterial activity lasts only 2 to 4 hours. Insert two sponges/tampons side by side if the patient has a large nasal cavity. It is important to instruct the patient to keep the packing moist with saline nasal drops when leaving any nasal packing in place.

Removal of the sponge/tampon is simple and quick. Apply 1 to 2 mL of tap water, saline, or a diluted vasoconstrictor in a drop-wise fashion to the tip of the sponge/tampon in the nostril. This will thoroughly hydrate the packing and ensure that it can be withdrawn without causing further trauma. Allow 5 to 10 minutes to ensure that the packing is completely hydrated. Grasp the end of the sponge/tampon with a hemostat. Place a kidney basin under the patient's nose. Pull quickly and parallel to the floor of the nasal cavity to remove the packing. Epistaxis after removal is often due to dislodgement of the clot. Use an absorbable pack or silver nitrate to stop the bleeding. Look at the sponge/tampon to identify the blood spot and the location of the bleeding.

INFLATABLE NASAL BALLOON CATHETERS

The development of plastic inflatable balloon catheters has greatly simplified the management of epistaxis as they are easy to use and quick to place. Nasal balloon catheters are available in a variety of

FIGURE 205-13. Examples of some inflatable nasal balloon catheters.

sizes and shapes with anterior balloons, posterior balloons, or dual balloons (**Figure 205-13**). The anterior balloon, often covered with a carboxycellulose outer layer to promote platelet aggregation, fills the nasal cavity and acts as an anterior pack. The posterior balloon occludes the nasopharynx and acts as a posterior pack. The inflatable balloons are more expensive than other methods used to manage epistaxis. The increased cost is offset by decreased Emergency Physician contact time as compared with that required for petrolatum gauze packing. The balloons have a maximal inflatable volume that is manufacturer-specific, on the packaging, and on the balloon's inflation hub.

Prepare the equipment for an anterior epistaxis. Elect an anterior balloon catheter. A dual-balloon catheter may be used if an anterior balloon catheter is not available. Inflate the balloon with air to just below its maximum capacity. Observe and palpate the balloon for leaks. It may be inflated in a cup of water to look for leaks. Completely deflate the balloon and apply a lubricant over the catheter and balloon.

Insert the nasal speculum and identify the bleeding location. **Insert the catheter with the distal bevel toward the nasal septum.** This prevents the distal end of the catheter from getting caught on the turbinates, damaging the mucosa overlying the turbinates, and causing a second source of epistaxis. Advance the catheter along the floor of the nasal cavity until just the inflation hub is protruding from the nostril (**Figure 205-14**). Inflate the balloon with 10 mL less

FIGURE 205-14. Inflation of an anterior balloon catheter to control anterior epistaxis.

air than the maximum volume of the balloon (**Figure 205-14**). **Do not use saline or water to inflate the balloon.** Rupture of the balloon can result in aspiration if it is filled with liquid. **Do not inflate the balloon with more than the manufacturer's recommended volume.** The balloon may have been inflated larger than the nasal cavity if the patient complains of pain. Slowly deflate the balloon in 2 mL increments until the pain subsides.

Observe the patient for continued bleeding. Increase the volume of the balloon to the maximum volume if the patient does not complain of pain. The balloon may cause a bowing of the septum to the contralateral side. Pack the contralateral anterior nasal cavity to keep the septum in the midline if the bleeding continues. Observe the patient for further bleeding from the nostril or into the nasopharynx. Continued bleeding suggests that the source is high in the nasal cavity or posterior. **The inflatable balloons do not always fill the upper portion of the nasal cavity.** Deflate the balloon, pack the high anterior nasal cavity with Vaseline gauze, and reinflate the balloon. Observe the patient for continued bleeding that would require a posterior pack as described in the following sections.

RAPID RHINO

The Rapid Rhino Nasal Pac catheter (Smith & Nephew, Inc., Austin, TX) is a form of balloon catheter. The balloon is covered with a hydrocolloid fabric that is self-lubricating, is easy to insert, and promotes platelet aggregation. It is available in different lengths (i.e., 4.5, 5.5, and 7.5 cm) to accommodate children, anterior epistaxis, and posterior epistaxis. It is available in a unilateral balloon design and a bilateral balloon design with a single inflation port. The bilateral model allows for bilateral nasal packing with a single inflation port and maintains equal pressure on both sides of the nasal septum. Dip the fabric-covered balloon in sterile water for approximately 30 seconds to prelubricate it prior to insertion. Insert the balloon and inflate it as described previously. The advantage to this product is the ease of insertion, minimal bleeding upon removal, and patient comfort.²⁷⁻²⁹

ENTaxis NASAL PACKING

An anterior nasal packing is the ENTaxis (**Figure 205-15**). It is composed of a natural polymer derived from seaweed and contains calcium alginate.³⁰ The packing provides hemostasis, has healing properties, and is atraumatically inserted and removed. Hydration with normal saline activates the calcium alginate and makes

FIGURE 205-15. The ENTaxis nasal packing. (Boston Medical Products, Westborough, MA.)

it pliable. The packing expands 300% and conforms to the anterior nasal cavity. It activates platelet aggregation to provide hemostasis, keeps the nasal mucosa moist, and gels into a smooth surface that allows easy removal.

Prepare the packing. The ENTaxis is packaged in a plastic tray with a tear-off paper lid. Peel the lid completely off the tray. Fill the tray with normal saline to saturate the packing. Remove the hydrated packing from the tray. Squeeze out the excess saline from the packing.

Insert a nasal speculum. Grasp the packing on the end opposite the string with a bayonet forceps. Insert the packing along the floor of the nasal cavity. Continue to insert the packing in an accordion-like fashion until the entire packing is within the nasal cavity. The packing will expand and gel to fill the nasal cavity. Secure the string to the patient's cheek or nose with a piece of tape.

Removal of the packing is simple and quick. The packing remains hydrated and in a gelled state while within the nasal cavity. Place a kidney basin under the patient's nose and remove the tape from the string on the patient's face. Grasp the packing with a bayonet forceps and gently withdraw the packing from the nasal cavity.

TOPICAL THROMBIN

Topical bovine thrombin is approved for the management of epistaxis. It works on sites of minor bleeding and oozing. The thrombin causes fibrinogen in the blood to clot without the requirement of platelet activation. The thrombin comes in many forms (e.g., dry powder, liquid in syringes, and liquid spray).

Insert a nasal speculum and find the bleeding source. Hydrate and mix the topical thrombin according to manufacturer directions. Attach the nasal delivery device. Insert the nasal delivery device into the nares and spray the thrombin solution onto the nasal mucosa. Remove the device and allow the solution to form a clot. Apply additional thrombin solution if the bleeding continues. Consider applying a piece of Gelfoam to the newly formed clot to support it.

THROMBIN-GELATIN MIXTURES

The Floseal Hemostatic Matrix (Baxter Healthcare Corporation, Hayward, CA) and the Surgiflo Hemostatic Matrix (Ethicon, Patterson, NJ), among others, are composed of human-derived thrombin and bovine-derived gelatin. They stop bleeding fast (approximately 2 minutes) in up to 97% of cases.^{19,31} The thrombin-gelatin matrix begins to break down in 3 to 5 days and is fully dissolved by 7 days. Floseal does not require platelet activation, allowing it to function in patients taking aspirin and other antiplatelet medications. Floseal and Surgiflo are provided in components that must be mixed. The process is more complicated than other thrombin products and can take several minutes. The kit contains all the required components and supplies. Attach one of the two applicator tips to the syringe containing the gelatin-thrombin solution.

Apply a small mound of the Floseal to the bleeding source. The Floseal must remain at the site for 2 minutes. Place a sterile saline-moistened gauze sponge over the Floseal mound to ensure it maintains a seal against the bleeding site. Remove the gauze after 2 minutes and inspect the site. If the gauze adheres to the clot or the Floseal, moisten it with sterile normal saline. Insert the applicator tip through the Floseal mound and deliver fresh Floseal to the bleeding site if bleeding persists. Remove any excess Floseal by gentle irrigation after the bleeding is controlled. Consider applying a piece of Gelfoam to the newly formed clot to support it.

The procedure for using Surgiflo is different. Reconstitute it in sterile water and draw it into a syringe. Apply the applicator tip onto the syringe. Place the applicator tip into the nasal cavity. Fill the nasal cavity from the back to the front and fill the nasal cavity

while withdrawing the syringe. Allow the mixture to gel and stop the bleeding.

WOUNDSEAL

WoundSeal powder (Bioline LLC, Sarasota, FL) was previously marketed as NoseBleed QR and WoundSeal for Nosebleeds. It is an over-the-counter product that comes in a variety of applications to control bleeding (Figure 205-16). It is marketed to control epistaxis and external wounds of all types. It consists of a powder containing a hydrophilic polymer and potassium ferrate. The powder is loaded onto an applicator swab and applied to the site of bleeding. When the powder comes in contact with blood, the polymer absorbs liquid and concentrates the red blood cells and plasma proteins under the powder to form a clot. The potassium ferrate releases iron to bind the blood proteins into a clot.

The WoundSeal powder is simple to apply. Open the blister pack. Roll the tip of the applicator stick in the powder to completely coat it. Roll the powder-coated applicator onto the nasal mucosa. Remove the applicator stick from the nasal cavity. Pinch the nostrils closed for 30 seconds. Reassess the nasal cavity for continued bleeding and the need for additional applications of the powder. Consider applying a piece of Gelfoam to the newly formed clot to support it.

ANKAFERD BLOOD STOPPER

Ankaferd Blood Stopper (ABS, Ankaferd Health Products LTD, Istanbul, Turkey) is a medicinal plant extract. It is approved in Turkey for the management of postsurgical dental bleeding and external hemorrhage.³² ABS is not currently available in the United States and many other countries. It induces the rapid formation of a hemostatic protein network to control hemorrhage that is that is not dependent upon coagulation factors and platelets.¹⁸ It has been successfully used to control epistaxis.³³ ABS is available in tampons and liquid spray that may provide a new method to control epistaxis in the future.

FIGURE 205-16. The WoundSeal and applicator.

TRANEXAMIC ACID (TXA)

Tranexamic acid (TXA) has recently emerged as a potential primary or adjunctive treatment for epistaxis. TXA is an antifibrinolytic agent that reversibly binds to plasminogen. It inhibits plasminogen from binding to fibrin. This interaction prevents plasminogen activating thrombin and prevents clot dissolution.³⁴ TXA is a synthetic analog of lysine. It is available in 100 mg/mL solution for injection and oral tablets. An Internet search revealed liquid TXA to be inexpensive (e.g., \$1.37/mL) and more cost effective than other equipment used to treat epistaxis.

A study evaluated 216 patients with presumed anterior epistaxis and randomized them to receive packing soaked in TXA (500 mg in 5 mL) or packing soaked in lidocaine with epinephrine followed by anterior nasal packing for 3 days.³⁵ This study demonstrated a statistically significant decrease in time to epistaxis resolution and discharge from the Emergency Department in the TXA group. Topical TXA is largely considered safe for use without complications.^{36,37} A Cochrane review evaluated the effects of topical TXA administration to control bleeding in patients undergoing surgery or those with epistaxis.³⁶ This review suggested that topical application of TXA reduces bleeding with no significant increase in thromboembolic events. TXA has been used successfully in epistaxis for patients taking oral anticoagulants.³⁸

POSTERIOR EPISTAXIS MANAGEMENT TECHNIQUES

A posterior source of the bleeding must be considered when epistaxis is bilateral, brisk, or not controlled with anterior nasal packing. It is estimated that 5% of all cases of epistaxis originate from a posterior source.³⁹ **The placement of a posterior nasal pack is extremely uncomfortable.** The patient usually requires intravenous sedation and analgesia (Chapter 159) in addition to the topical anesthesia. Consider spraying the patient's soft palate, uvula, and oropharynx with a topical anesthetic spray (e.g., Cetacaine). This will minimize their gag reflex during the placement of the posterior pack. **Endotracheal intubation is sometimes required to appropriately visualize and control posterior epistaxis.**

The rationale behind placing a posterior pack is that the occlusion of the choanal arch provides a semirigid buttress against which anterior nasal packing may be placed, allowing adequate hemostasis to be achieved. This buttress may be formed from either a gauze pack, a 30 mL Foley catheter (e.g., size 12 to 14 French), an expandable nasal sponge/tampon, or an inflatable nasal balloon catheter. The Foley catheter and inflatable nasal balloon catheter are most easily tolerated by the patient. The inflatable nasal balloon catheter is the easiest to place and has two balloons that serve as anterior and posterior packs. **An anterior nasal pack is always required on the side of a posterior pack.** Strongly consider inserting a contralateral anterior nasal pack to maintain the septum in the midline. **Epistaxis that requires posterior packing should be managed in conjunction with an Otolaryngologist. Admission to a monitored setting is warranted due to the potential for complications (e.g., dysrhythmias, hypoxia, hypoventilation, and airway compromise).**

TRADITIONAL (GAUZE ROLL) PACKING

The traditional technique of posterior nasal packing involves using rolled gauze, dental rolls, or tonsil packs placed through the oropharynx (Figure 205-17). This technique is difficult, time-consuming, and messy; requires many supplies; and is not well tolerated by the awake patient. Easier and quicker techniques exist and for these reasons this technique is not often performed.

Prepare the equipment. Gather the required equipment on a bedside procedure table. Use 3 inch long dental rolls or tonsil packs. An alternative is to use 3 inch wide and 36 inch long petrolatum gauze formed into a tight cylindrical roll (Figure 205-17A). Tie two pieces of umbilical tape or 0 silk suture around the pack to divide it into thirds (Figure 205-17A).

Anesthetize and vasoconstrict both nasal cavities. Apply a topical anesthetic spray to the soft palate, uvula, and oropharynx. Lubricate a red rubber catheter. Pass the red rubber catheter through one nostril and along the floor of the nasal cavity. Advance the catheter so that the tip is visible in the patient's oropharynx. Grasp the tip of the catheter with a hemostat or forceps and pull it out the patient's mouth (Figure 205-17B). Clamp the free ends of the catheter together. Pass a second red rubber catheter through the other nostril and out the patient's mouth.

Insert the posterior pack. Tie the free end of one piece of the umbilical tape or silk surrounding the packing to the distal end of one red rubber catheter exiting the patient's mouth (Figure 205-17C). **Tie the knots tightly.** Tie the second piece of umbilical tape or silk to the second red rubber catheter. Pull the proximal ends (i.e., the portion exiting the nostrils) of both red rubber catheters until the packing is against the choanae (Figure 205-17D). It may be necessary to place a finger into the patient's mouth and push the pack behind the soft palate and uvula if it gets caught (Figure 205-17D). Place a hemostat on both pieces of umbilical tape exiting the nostrils. Apply slight traction with the hemostat to maintain the posterior pack against the choanae. Instruct an assistant or the patient to hold the hemostat. Untie or cut the red rubber catheters from the umbilical tape or silk sutures.

Place an anterior pack and secure the posterior pack. **An anterior nasal pack is always required when placing a posterior nasal pack.** The anterior pack may be an expandable sponge/tampon, petrolatum gauze, or a balloon catheter (Figure 205-17E). Tie the umbilical tape or silk exiting each nostril together (Figure 205-17F). **Always place a piece of cotton or gauze between the knot and the columella to prevent pressure necrosis (Figure 205-17F).** Tie the umbilical tape or silk snugly but not too tight to hold the posterior pack in place and minimize pressure on the choanae and the columella. Tape the umbilical tape or silk exiting the patient's nostril and mouth to their face (Figure 205-17F).

Removal of this packing is simple and requires several stages. Remove the anterior packing. Thoroughly examine the mucosa to make sure that the epistaxis has not restarted. Suction any clots and blood from the nasal cavity. Rebleeding requires the placement of a new anterior pack if it cannot be controlled with an absorbable dressing or silver nitrate. Cut the knot securing the umbilical tape or silk around the columella. Pull the pieces of umbilical tape or silk exiting the patient's mouth to remove the posterior pack completely.

FOLEY CATHETER TECHNIQUE

A Foley catheter may be used to provide a posterior buttress. Using a Foley catheter to control posterior epistaxis is relative quick, easy, and simple as it does not require the preparation of specialized equipment. Select a 12 or 14 French Foley catheter with a 30 mL balloon. Inflate the balloon with air and ensure the integrity of the balloon. Some Emergency Physicians cut off the portion of the Foley catheter distal to the balloon as they believe that the distal tip is irritating to the patient and may stimulate their gag reflex. The practice of cutting off the distal tip is based purely on Emergency Physician preference. Be careful to not cut the balloon or its attachment to the catheter.

Lubricate the distal third of the Foley catheter. Insert the Foley catheter into the nostril and along the floor of the nasal cavity.

FIGURE 205-17. The traditional technique of placing a posterior nasal pack. **A.** Preparation of the pack. **B.** A red rubber catheter inserted through the nostril and pulled out the mouth. **C.** The pack is attached to the two red rubber catheters. **D.** The pack is pulled into place. Use a finger to pass the pack around the soft palate and uvula. **E.** An anterior nasal pack has been placed. **F.** The ties of the posterior pack are secured.

Advance the catheter until the tip is visible in the patient's oropharynx. Inflate the balloon with 7 to 10 mL of air. **Do not use saline as the fluid can result in aspiration if the balloon ruptures.** Withdraw the catheter to lodge the balloon against the choanal arch (**Figure 205-18A**). If the balloon withdraws into the nasal cavity, advance it back into the nasopharynx. Add an additional 3 to 5 mL of air and withdraw the catheter. Continue the process by adding 3 to 5 mL aliquots of air until the balloon lodges against the choanal arch. Inflate the balloon with an additional 3 to 5 mL of air and until

the soft palate just begins to bulge. **The balloon is overinflated if the soft palate bulges or the patient experiences pain.**

Place an anterior pack and secure the Foley catheter. Apply slight traction to maintain the balloon against the choanal arch. Instruct an assistant or the patient to hold the Foley catheter. Place the anterior pack using an expandable sponge/tampon, petrolatum gauze, or a balloon catheter. **Place a piece of cotton or gauze against the columella and nasal ala to prevent pressure necrosis.**⁴⁰ Place an umbilical clamp on the Foley catheter and over the protective

FIGURE 205-18. The Foley catheter technique. Insert a Foley catheter along the floor of the nasal cavity until the tip is visible in the patient's oropharynx. **A.** Inflate the balloon and withdraw the catheter to lodge the balloon against the choanal arch. **B.** Secure the Foley catheter.

padding (Figure 205-18B). The clamp must hold the balloon against the choanal arch without applying pressure to the choana or columella.

Removal of this packing is simple and requires several stages. Cut the open loop of the umbilical clamp with a scissors. Open the jaws of the clamp and remove them from the Foley catheter. **Always maintain a grasp of the catheter and apply slight traction to keep the balloon in place.** Remove the anterior packing. Thoroughly examine the mucosa to make sure that the epistaxis has not restarted. Suction any clots and blood from the nasal cavity. Rebleeding requires the placement of a new anterior pack if it cannot be controlled with an absorbable dressing or silver nitrate. Deflate the balloon and pull the catheter out the patient's nostril.

EXPANDABLE NASAL SPONGES/TAMPONS

Many Emergency Physicians prefer to use an 8 or 10 cm sponge/tampon rather than the other techniques of posterior packing as this technique is easy, quick, simple, and inexpensive. The technique for insertion and removal is the same as for the anterior packing technique described previously. A combination device with an anterior nasal sponge/tampon and a posterior balloon is available. It provides better posterior hemostasis than a sponge/tampon alone.

INFLATABLE DUAL-BALLOON NASAL CATHETERS

A dual-balloon catheter can be used when a posterior pack is required. These catheters come in many types and styles (Figure 205-13). They are expensive, easy to use, and quickly placed. The smaller distal balloon obstructs the choanal arch and acts as a posterior pack (Figure 205-19). The larger proximal balloon fills the nasal cavity and acts as an anterior pack (Figure 205-19). The distal balloon holds 10 mL and the anterior balloon holds 30 mL in most dual-balloon systems. Note the manufacturer's maximum volume recommendations on the package and on the inflation ports of the balloons.

Prepare the equipment. Fully inflate both balloons with air. Observe and palpate the balloons for leaks. They may also be inflated in a cup of water to look for leaks. Completely deflate both balloons and apply a lubricant over the catheter and balloons.

Insert the catheter with the distal bevel toward the nasal septum. This prevents the distal end of the catheter from getting caught on the turbinates, damaging the mucosa overlying the turbinates, and causing a second source of epistaxis. Advance the catheter along the floor of the nasal cavity until the distal tip is visible in the patient's oropharynx.

FIGURE 205-19. Placement of a dual-balloon catheter.

Inflate the distal balloon with 4 to 5 mL of air. **Do not use saline or water to inflate the balloon.** Rupture of the balloon can result in aspiration if it is filled with liquid. Withdraw the catheter to lodge the balloon against the choanal arch (Figure 205-19). If the balloon withdraws into the nasal cavity, advance it back into the nasopharynx. Add an additional 2 to 3 mL of air and withdraw the catheter. Continue this process until the balloon lodges or the maximum balloon volume is reached. Inflate the anterior balloon with 20 to 25 mL of air.

Observe the patient for bleeding. Inflate both balloons with additional aliquots of air until the bleeding stops or the maximum balloon volume is reached. The balloon does not always fill the high anterior nasal cavity. Deflate the anterior balloon, pack the high anterior nasal cavity with Vaseline gauze, and reinflate the anterior balloon if the bleeding continues. Place an anterior pack on the contralateral side if the bleeding continues to maintain the septum in the midline and apply pressure to the ipsilateral nasal cavity.

SPHENOPALATINE ARTERY BLOCK

This technique is used only as a last resort when an Otolaryngologist is not available, the hemorrhage is unremitting, and other methods to control the epistaxis have failed. Local anesthetic solution is injected into the pterygopalatine canal to occlude the sphenopalatine artery. The local anesthetic solution can cause pressure necrosis of the adjacent nerves.

Place the patient supine with their mouth open. Apply a topical anesthetic spray to the hard palate. Identify the greater palatine foramen. Insert a 27 gauge needle into the mucosa of the hard palate, 1 cm medial to the gum line between the junction of the second and third maxillary molars. Probe this area with the needle until it falls into the greater palatine foramen. Inject 0.25 mL of local anesthetic solution containing epinephrine into the mucosa overlying the greater palatine foramen. Arm a 3 or 5 mL syringe containing local anesthetic solution with epinephrine with a 22 or 25 gauge needle. Insert the needle approximately 25 to 28 mm into the greater palatine foramen and inject 3 mL of the local anesthetic solution.

SURGICAL INTERVENTION

Consult an Otolaryngologist when the epistaxis is difficult to control by the described methods above. Surgical therapy may include septoplasty, endoscopic cauterization, arterial ligation (e.g., internal maxillary artery, sphenopalatine artery, anterior and posterior ethmoid arteries, external carotid artery), or embolization by an Interventional Radiologist.⁴¹⁻⁴⁵ Surgical and angiographic measures have not been shown to have benefits in regard to morbidity and mortality when compared with packing.⁴⁶⁻⁴⁸ **Packing should be attempted first with surgical and angiographic measures reserved for refractory cases.**

PEDIATRIC CONSIDERATIONS

Epistaxis is a common childhood symptom that may prompt an evaluation in the Emergency Department.⁸ The management of a child with acute epistaxis is straightforward. The source of bleeding is typically from the anterior one-third of the nasal septum just posterior to the squamous-mucosal junction in most children. The etiology is often due to digital manipulation, infection, allergic rhinitis, a coagulopathy, a foreign body, trauma, medications, a neoplasm, or recent surgery.⁴⁹ Epistaxis in the neonate and infant is rare.⁵⁰ Consider nonaccidental trauma (i.e., abuse) in this group.⁵⁰

The principles of management in the pediatric population are like those of adult patients. Active bleeding requires immediate attention. Assess the child for any hemodynamic instability or airway compromise. Obtain a brief history during the initial stages of treatment. The minimal equipment required for initial evaluation

includes a headlight, Yankauer suction, Frazier tip suction, a small nasal speculum, and a tongue depressor. Additional supplies may be required for the clinical situation. A more comprehensive list of equipment and medications has been outlined earlier in this chapter.

Manage any life-threatening injuries and ensure hemodynamic stability. The goal is to identify the bleeding source. Apply an anesthetic and vasoconstrictor. Evacuate any remaining clot from the nasal airway and inspect the mucosa. Cauterize the vessel with silver nitrate if the bleeding source is identified. Apply a thin piece of oxidized cellulose (i.e., Surgicel) or Gelfoam that has been impregnated with an antibiotic ointment over the site to help stabilize the clot. Place an anterior nasal pack if chemical cauterization fails to control the bleeding. Expandable nasal sponges/tampons are readily available and are relatively easy to place. Trim the sponge/tampon to an appropriate length prior to insertion. Consult an Otolaryngologist if the bleeding cannot be controlled, if there are concerns that the bleeding source is from a posterior location, or for any postsurgical patient.

The underlying cause should be identified and treated.^{3,51} Antibiotic ointment and nasal saline should be used to minimize crusting and to hydrate the mucosa for patients with epistaxis secondary to digital manipulation. Antibiotic therapy is indicated in cases of acute sinusitis and adenoiditis. Coagulopathy must be considered when a patient presents with recurrent epistaxis. Up to 30% of children with recurrent epistaxis have a coagulopathy, with Von Willebrand's disease the most common disorder identified.⁵² Laboratory testing should include a complete blood count, prothrombin time, partial thromboplastin time, and international normalized ratio in patients whose history suggests heavy bleeding, recurrent bleeding, or a personal or family history of bleeding abnormalities.²⁰

AFTERCARE

The postprocedural care of patients with anterior epistaxis is just as important as the initial control of bleeding. The recommendation to place patients on prophylactic antibiotics after nasal packing remains highly controversial and is not routinely indicated.⁵³⁻⁵⁷ The historic rationale for prophylactic antibiotics is due to a perceived risk of developing sinusitis and toxic shock syndrome. No randomized controlled trials exist evaluating the utility of prophylactic antibiotics after epistaxis. One study demonstrated no changes in microbiological flora before and after anterior nasal packing.⁵⁵ Another observational study found no association between the use of prophylactic antibiotics after anterior nasal packing and infectious complications (e.g., sinusitis or toxic shock syndrome).⁵⁶ **The authors do not recommend routine prophylactic antibiotics in most cases of anterior packing.** Consider antibiotic prophylaxis in cases of posterior packing and preference of the consulting Otolaryngologist. Routine use of antibiotics may select for resistant organisms.⁵⁹ Antibiotics are recommended for immunocompromised patients with nasal packing. Choices for prophylactic antibiotic therapy include amoxicillin-clavulanate, cephalexin, or trimethoprim-sulfamethoxazole to cover *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*.

Patients with significant epistaxis should follow up with an Otolaryngologist within 24 to 48 hours. Malignancies or other serious etiologies of epistaxis remain rare. Patients presenting with epistaxis should have follow-up care with an Otolaryngologist for a thorough nasopharyngeal examination. Remove the packing in 48 to 72 hours if the patient experienced only minimal blood loss and is hemodynamically stable.

Inform the patient that the anterior pack is uncomfortable. Acetaminophen will typically provide adequate analgesia. **Avoid aspirin-containing compounds and nonsteroidal anti-inflammatory**

drugs that can contribute to further bleeding. Opiates should also be used with caution as they can cause nausea, sedation, and vomiting. Patients on warfarin may generally continue their current regimen. Active reversal of anticoagulation is generally not needed provided their international normalized ratio is not supratherapeutic. **Instruct the patient to apply saline nasal spray to the packing or each nostril three or four times per hour while awake.** The use of a humidifier at home will aid in preventing drying of the packing or the nasal mucosa. **The patient must avoid nose picking and nose blowing.** Instruct the patient on the proper technique to apply pressure on the nose if bleeding restarts. Such pressure should be maintained continuously for 20 minutes. Instruct the patient to return to the Emergency Department if bleeding persists. The patient should also return for increased nasal pain, fever, or any symptoms related to blood loss (e.g., chest pain, dyspnea on exertion, dizziness, lightheadedness, shortness of breath, or syncope).

Patients with unstable vital signs, uncontrollable bleeding, posterior packing, or serious concomitant medical problems will require hospitalization. Patients with posterior nasal packs require consultation with an Otolaryngologist and admission to a telemetry or intensive care unit. They must be monitored for respiratory distress, hypoxia, hypotension, anemia, and cardiac sequelae. It has been estimated that 40% of patients with posterior nasal packing eventually require intubation.⁵⁸ The nasal ala and columella must be evaluated continually to prevent pressure necrosis. Consider the use of antibiotics in posterior packing.⁵⁹

Patients with a posterior nasal pack may experience hypoxemia and hypercarbia. The etiology of this phenomenon, called the nasopulmonary reflex, is unknown. The PaO₂ may decrease 7 to 15 mmHg and the PaCO₂ may increase 7 to 15 mmHg. The nasopulmonary reflex is more worrisome in patients with underlying lung disease or comorbid conditions.

The association between hypertension and epistaxis remains complicated as patients with epistaxis frequently present with an elevated blood pressure.³ Epistaxis also appears to be more common in hypertensive patients.⁶⁰ Hypertension is rarely the direct cause of epistaxis and more commonly the associated anxiety with epistaxis results in an abrupt increase in blood pressure.^{61,62} Therapy should initially focus on control of the hemorrhage, reducing discomfort, and reducing anxiety rather than reduction of the blood pressure.

Local vasoconstriction, cautery, and/or packing will accomplish resolution of epistaxis for most patients. Administration of appropriate blood products (i.e., fresh frozen plasma, platelets, or recombinant factor VIIa) may be useful in patients with inherited or acquired bleeding disorders or platelet dysfunction. A risk-benefit analysis and discussion should occur on a case-by-case basis. A transfusion of packed red blood cells must also be considered in patients with significant bleeding, anemia, and ongoing blood loss.

COMPLICATIONS

The complications associated with epistaxis are variable, wide ranging, and estimated to be from 2% to 69%.⁴⁷ Epistaxis may be complicated by hemorrhage, hypoxemia, hypovolemia, circulatory collapse, and airway compromise. Complications resulting from the treatment of epistaxis include nasal septal perforation, sinusitis, otitis media, toxic shock syndrome, aspiration, alar necrosis, and hypoxia from intrapulmonary shunting due to the nasopulmonary reflex.⁶³ A single-center retrospective study showed recurrence of epistaxis and return to the Emergency Department occurred in approximately 26% of patients.⁶⁴ Silver nitrate cauterization had the highest success rate in cessation of epistaxis at 80% while recurrence occurred the most often in those treated with nasal clips at 59%, Meroel packing at 26%, and petroleum gauze packing at 42%.⁶⁴

Most complications can be prevented by using proper technique, providing supplemental oxygen when not contraindicated, arranging appropriate hospitalization if indicated, obtaining an Otolaryngology consultation, and arranging for adequate follow-up.⁶⁵ Topical lidocaine in the nasal cavity can cause complications.⁶⁶ Always calculate the dose used and assume that the entire dose will be absorbed. The nasal mucosa is very absorbant and the lack of a vasoconstrictor can result in increased absorption.

SUMMARY

Epistaxis is a common condition that affects 10% to 13% of the general population. The key to successful management includes a prompt and thorough evaluation of the patient, an accurate diagnosis of the problem, and rapid control of the bleeding. There has been a significant expansion in therapeutic options (e.g., TXA) to treat epistaxis. Almost all cases of epistaxis stem from an anterior source and can be controlled with either direct pressure, chemical cautery, or nasal packing. Posterior bleeding requires the use of a posterior pack and anterior packing. There is insufficient evidence supporting the routine use of prophylactic antibiotics in patients with anterior packing. Consider prophylactic antibiotics in all patients with nasal packing to prevent sinusitis and toxic shock syndrome. Follow-up is required in 24 to 72 hours with an Otolaryngologist or in the Emergency Department to remove the nasal packing.

Laryngoscopy

Steven Charous

INTRODUCTION

Evaluation of the larynx can be crucial in the diagnosis and management of common and life-threatening disorders. The approach to the patient with laryngeal dysfunction begins with obtaining a complete history. Symptoms may be related to any of the three primary functions of the larynx. These are protection of the lower airway from aspiration, a conduit of the airway, and phonation. Symptoms may include aspiration, cough, dysphagia, odynophagia, dyspnea, or hoarseness. Otalgia may be a referred symptom from the larynx and transmitted by a branch of the vagus nerve. Information regarding patient age, onset, duration, severity, and progressive nature of the process is necessary. Determine the patient's past medical history including prior intubations, neck trauma, reflux esophagitis, similar previous episodes, and other systemic diseases. The social history, including smoking and alcohol usage, needs to be investigated. Medications, allergies, and over-the-counter drugs should be reviewed.

Perform a physical examination, including a complete head and neck examination, once the history has been obtained.¹ Listen for stridor and watch for accessory muscle breathing. Consciously and critically evaluate the patient's voice to hear breathiness, clarity, and volume. Inspect the ears, nose, oral cavity, oropharynx, and nasopharynx. Careful palpation of the neck is extremely important. Note any lymphadenopathy and neck masses. This must include their size, location, tenderness, and mobility. Palpate the larynx and note any crepitus. The lack of crepitus on lateral movement of the larynx over the vertebral bodies can be indicative of a laryngeal or hypopharyngeal mass. Note any movement with swallowing and asymmetry. This can help in determining the extent of a disease process.

Visualize the larynx after performing a complete history and physical examination with the exception of true airway emergencies. This allows the Emergency Physician to examine the larynx in context to the patient's symptoms and other physical findings. It also allows a rapport to develop between the patient and Emergency Physician prior to undergoing a mildly invasive procedure.

There are four methods of performing indirect laryngoscopy: mirror laryngoscopy, nasal flexible fiberoptic laryngoscopy, oral flexible fiberoptic laryngoscopy, and rigid telescopic laryngoscopy. The following is a complete description of the procedure involved in performing each of these techniques. An excellent pictorial source for viewing normal and pathologic conditions of the larynx may be found in Bruce Benjamin's publications.^{2,3} **Table 206-1** reviews the advantages and disadvantages of each procedure. Each method allows visualization of the larynx with different degrees of distortion (**Figure 206-1**).

ANATOMY AND PATHOPHYSIOLOGY

The larynx occupies the central neck and is located within the hypopharynx (**Figures 206-2 and 206-3**).⁴⁻⁶ Lateral to the larynx are the pyriform sinuses and the pharyngeal recesses that are the primary route for food to pass into the esophagus. The basic framework of the larynx consists of the thyroid cartilage, cricoid cartilage, epiglottic cartilage, arytenoid cartilage, and the hyoid bone. The shield-like thyroid cartilage supports the soft tissues of the larynx. It is connected to the hyoid bone via the thyrohyoid membrane and is attached to the cricoid cartilage via the cricothyroid membrane and at the cricothyroid joint. **The signet ring-shaped cricoid cartilage is the only complete cartilaginous ring in the larynx.** On top of its posterior portion sits the paired arytenoid cartilages. The arytenoid cartilages are somewhat shaped like an inverted "T." Each has a body, a muscular process, and a vocal process. The aryepiglottic folds connect the epiglottis to the top portion of the arytenoid body. The vocal ligament attaches the vocal process to the thyroid cartilage. The cricoarytenoid muscles attach to the muscular process. The epiglottic cartilage is leaf-shaped and forms the anterior wall of the laryngeal entranceway. Its main portion projects posterior to the tongue base. It folds downward over the larynx during swallowing to aid in protecting the laryngeal opening from aspiration.

The muscles associated with the larynx may be divided into extrinsic muscles and intrinsic muscles. The extrinsic muscles move the larynx as a unit and can be further subdivided into those muscles that elevate the larynx (i.e., the stylohyoid, digastric, geniohyoid, and stylopharyngeus) and those that depress the larynx (i.e., the omohyoid, sternohyoid, and sternothyroid). The intrinsic muscles are involved with vocal cord mobility and all cause adduction with the exception of the cricoarytenoid muscle that causes abduction. Innervation to the intrinsic laryngeal muscles is via the recurrent laryngeal nerve, a branch of the vagus nerve (cranial nerve X). The cricothyroid muscle is the only muscle innervated by the external branch of the superior laryngeal nerve, a branch of the vagus

TABLE 206-1 Summary of the Advantages and Disadvantages of the Different Techniques Used to Perform Indirect Laryngoscopy

	Hand-held mirror	Per-oral flexible endoscopy	Per-oral rigid endoscopy	Nasal flexible endoscopy
Gag reflex	Moderate	Moderate	Moderate	Minimal
Visual clarity	Good	Good—distorted	Superior	Good—distorted
Anesthetic	Occasionally	Yes	Occasionally	Yes
Observe larynx during speech	No	No	No	Optional

Approximate equipment cost	Minimal	\$4500	\$4500	\$4500
Documentation possible?	No	Yes	Yes	Yes

nerve. All of the laryngeal muscles and cartilages are covered with respiratory epithelium.

Just superior to the vocal cords is a recess called the laryngeal ventricle. Just superior to the ventricle are the false vocal folds. These are rounded protrusions rich in mucus-secreting glands. The supraglottic larynx is defined as that portion of the larynx extending from the tip of the epiglottis to the laryngeal ventricle. The glottic larynx contains the true vocal cords and extends approximately 5 to 7 mm inferiorly. The subglottis extends from the inferior glottis to the inferior edge of the cricoid cartilage.

The primary function of the larynx is to protect the airway from the aspiration of food particles. A complex reflex arc, with the glossopharyngeal nerve (cranial nerve IX) mediating the sensory arm and

the vagus nerve (cranial nerve X) mediating the motor arm, occurs with swallowing. With each swallow the larynx elevates, the aryepiglottic folds squeeze medially, the epiglottis folds posteriorly over the larynx, and the true and false vocal folds close tightly. These actions allow the food bolus to pass around the larynx, into the pyriform sinuses, and subsequently into the esophagus. Any alteration or disturbance in the reflex arc may predispose a patient to aspiration.

Phonation occurs with adduction of the vocal cords as air passes from the trachea through the vocal cords. The mucosa overlying the muscles of the vocal cords undulates and the two vibrating vocal cords produce sound. Anything that alters the mucosal wave of the vocal cords, impairs adduction, or changes the configuration of vocal cord alignment will result in decreased phonatory

FIGURE 206-1. Visualization through the endoscopes. **A.** Endoscopic view through the 90° rigid telescope. Note the magnification, clarity, and breadth of view. **B.** Endoscopic view through the “chip-in-tip” scope. Note the larger field of vision with minimal distortion. **C.** Endoscopic view through flexible fiberoptic scope. Note the distortion and limited view as compared to the view through the rigid scope.

FIGURE 206-2. The laryngeal framework. **A.** Lateral view. **B.** Superior view.

performance. Note that mucosal wave abnormalities can only be observed with videostroboscopy of the larynx. Many things can change a person's voice. This includes but is not limited to inflammation, thick mucus, polyps, granulomas, vocal cord paralysis, and tumors. Be careful and define hoarseness as a change in the patient's vocal quality. What may be normal for one patient may not be for another.

The larynx is crucial in respiratory activity. Inspiration signals the recurrent laryngeal nerve to stimulate vocal cord abduction. Impairment in abduction, unilaterally or bilaterally, can lead to respiratory compromise. Tumors, polyps, or edema located in the supraglottis, glottis, or subglottis can lead to airway compromise.

INDICATIONS

Have a very low threshold for examining the larynx. The diagnostic value of laryngoscopy greatly outweighs the minimal discomfort associated with the quick procedure. Any patient presenting with an allergic reaction, angioedema, acute hoarseness or voice changes, symptoms of aspiration, shortness of breath, a foreign body sensation, hemoptysis, stridor, exposure to ingested caustic agents, exposure to hot fumes or gasses, exposure to caustic fumes or gasses, or any other symptom that may be related to the larynx should have laryngoscopy performed as part of a complete physical examination including predicting a difficult airway.¹⁻¹⁰

CONTRAINDICATIONS

There are no absolute contraindications for laryngoscopy. Patients with severe respiratory compromise, such as a child with suspected epiglottitis, should have laryngoscopy performed in

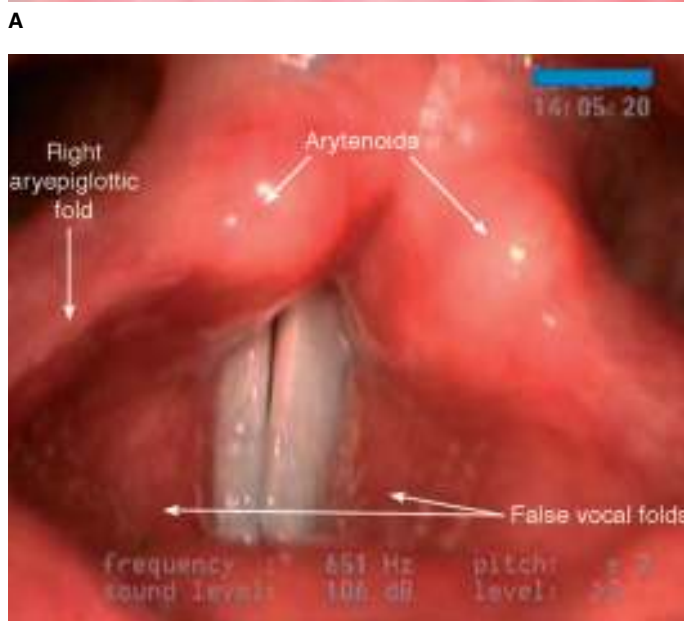

FIGURE 206-3. Endoscopic view of the laryngeal anatomy. **A.** Vocal cords open. **B.** Vocal cords closed.

the Operating Room (or in a controlled area) with an Anesthesiologist, intubation equipment, and tracheotomy instrumentation ready for use. **Performing laryngoscopy in the respiratory distressed patient can lead to increased distress and ventilatory collapse if laryngospasm ensues. Experienced personnel should perform laryngoscopy in a patient with a high-grade airway obstruction with caution and preparedness for intubation, but the exam should most likely still be performed as the information gained is crucial for planning patient care.** In general, the patient must be able to follow instructions and cooperate with the examination.

EQUIPMENT

ANESTHESIA AND VASOCONSTRICTION

- 4% lidocaine (preferred for nasal anesthesia)
- 10% lidocaine spray

- 20% benzocaine spray
- 2% tetracaine spray
- 4% cocaine
- 3% ephedrine, Neo-Synephrine spray, or oxymetazoline spray
- Cotton pledgets

■ SCOPES

- #4 or #5 dental mirror, with or without magnification
- 3 to 5 mm diameter flexible fiberoptic laryngoscope; 3 mm is better for children
- 90° rigid laryngoscope
- Video laryngoscope (Chapter 20, optional)

■ LIGHT SOURCES

- Headlight for mirror examinations
- 125 to 250 watt halogen or xenon light sources for fiberoptic laryngoscopes

■ MISCELLANEOUS

- Alcohol lamp, heated beads, or glass of warm water for mirror examination
- 4×4 gauze squares
- Water-soluble lubricant
- Antifog solution
- Video camera and equipment for teaching and photodocumentation (optional)

Set up all of the required equipment on a bedside procedure table (Figure 206-4). Prepare several different endoscopes, if available. If one fails, or is inadequate, another will be immediately available. The availability of multiple endoscopes allows the Emergency Physician to choose the scope and technique of their choice.

The flexible fiberoptic scope is composed of fiberoptic strands and lenses along its length. Do not manipulate or bend it into acute angles. Do not place objects onto the scope. Do not use abrasive materials (i.e., gauze, paper towels) to wipe the lens at the end of the fiberoptic cord.

FIGURE 206-4. Basic equipment required for examination of the larynx in the ambulatory setting. Included are the rigid 90° telescope, dental mirror, flexible fiberoptic scope, gauze, oral anesthetic, antifog solution, and a light source. Not included is topical spray for nasal decongestion and anesthesia.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. **Patient reassurance and relaxation are of the utmost importance in obtaining excellent visualization of the larynx.** This can be achieved by reviewing what can be expected from the patient's perspective, by reassuring them of the minimal discomfort, and by reassuring them of the short duration of the procedure. Topical anesthesia to the nasal or oral mucosa can induce the sensation of not being able to breathe or swallow because of the lack of sensory input. Informing the patient of this sensation prior to its use is extremely helpful in preventing a panicked patient. Alternatively, using only a vasoconstrictive agent and not a topical anesthetic may be more appropriate and tolerated for transnasal endoscopies as the procedure itself is usually very well tolerated with minimal discomfort.

Patient positioning is crucial in obtaining laryngeal visualization in any per-oral technique. Place the patient sitting upright in a multipositional procedure chair or on a gurney with their legs together. Instruct the patient to lean slightly forward and to draw their chin forward. This aligns the larynx and the oropharynx in a vertical plane to allow visualization of the anterior portion of the larynx. Raise or lower the multipositional chair, or the gurney, so that the patient's mouth is at the examiner's eye level.

Patient cooperation and positioning are not crucial for flexible fiberoptic examination of the larynx performed through the nose. Place the patient, optimally, sitting upright with their head against a headrest. The headrest will prevent the common occurrence of the patient's head backing away during the examination. The examination with the patient in the supine position is technically more challenging as gravity pushes the tongue posteriorly and the scope falls against the posterior pharyngeal wall, both of which make visualization of the anteriorly placed larynx more difficult. However, in most instances, it can still be performed without significant problems.

The use of good lighting cannot be overemphasized when performing a mirror examination. Apply a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. The overhead light often hits the examiner in the head, casts shadows, and is too bright for the patient's eyes. It is also difficult to properly position as both of the examiner's hands must be used for the procedure.

TECHNIQUES

A systematic evaluation of the larynx and hypopharynx is necessary no matter what technique is used. Assess all of the airway structures including the base of the tongue, vallecula, epiglottis, aryepiglottic folds, true and false vocal cords, arytenoids, posterior pharyngeal wall, and pyriform sinuses. Visualize adduction and abduction of the vocal cords during phonation and inspiration. Visualize, if possible, the subglottis through the vocal folds looking for a narrowing or stenosis of the airway in the stridorous or respiratory compromised patient without other laryngeal findings. Use care to minimize contact with the laryngeal mucosa with whatever device is used to avoiding excessive gagging and allowing a comfortable and thorough examination.

THE MIRROR EXAMINATION

Determine whether the patient has a significant gag reflex. If so, apply topical anesthesia. Spray a topical local anesthetic agent (e.g., benzocaine, lidocaine, or tetracaine) onto the patient's palate, tonsillar pillars, posterior pharyngeal wall, and base of the tongue. The application of a topical anesthetic agent is optional if the patient

FIGURE 206-5. Proper positioning for an indirect mirror examination of the larynx. Both of the examiner's hands are braced against the patient for stability. Some patients require elevation of the upper lip with the examiner's left, or nondominant, middle finger.

does not have a significant gag reflex. Instruct the patient to keep their eyes open and focus on a distant object to diminish the gag reflex. Practicing the entire procedure once with the patient, without inserting the mirror, is often a more reassuring and efficient manner of performing indirect laryngoscopy.

Instruct the patient to protrude their tongue. Grasp the tongue firmly between the nondominant thumb and index finger with a neatly folded gauze square (**Figure 206-5**). **Do not apply excessive traction on the tongue.** This is counterproductive as it elevates the tongue and makes the patient uncomfortable. Place the nondominant middle finger against the upper teeth as a brace. It may also be used to elevate the upper lip if needed. Instruct the patient to breathe through their mouth in a slow "panting-like" manner and to try to relax their tongue. This maneuver diminishes the gag reflex, elevates the palate, and lowers the tongue giving better access and visualization of the oropharynx.

Warm the mirror over an alcohol lamp, in heated beads, or in a cup of warm water to prevent fogging during the examination. Test the mirror back, if any type of heat is used, on the examiner's wrist for excessive heat that can injure the patient. An alternative is to use a mirror that has antifog solution placed on it to prevent fogging during the examination. Grasp the mirror with the dominant hand midway down the shaft like a pen (**Figure 206-5**). Brace the dominant fifth finger against the patient's face.

Introduce the mirror into the oral cavity with the glass surface parallel to the tongue (**Figure 206-5**). Instruct the patient to say a high-pitched "e-e-e" and hold it for 5 seconds just before the mirror touches and elevates the uvula and soft palate. The high-pitched "e-e-e" tilts the epiglottis forward and brings the vocal cords into view and apposition. Inform the patient that the "e-e-e" may sound like "ahhhhhh" while their tongue is held. This is helpful to them as they try to cooperate fully with the instructions. The Emergency Physician should simultaneously demonstrate the high-pitched sound as patients invariably will phonate in too low of a pitch for too short of a time period. Prevent gagging by asking the patient to phonate before the mirror actually touches the soft palate, avoiding touching the base of the tongue, and avoid touching the anterior tonsillar pillars.

Focus the headlight (or overhead light), as the patient phonates, on the mirror. Gently and slightly maneuver the mirror until the larynx is visualized. **Remember the orientation through the mirror. Left and right are the same but anterior and posterior have reversed orientation.** Perform a quick and systematic evaluation of the larynx and hypopharynx. Several reinsertions of the mirror are often required to obtain a complete examination.

PER-ORAL FLEXIBLE FIBEROPTIC LARYNGOSCOPY

The examiner will often have a more leisurely view of the larynx with this technique as compared to the mirror exam. Patients usually gag less and can tolerate this examination for longer periods of time.

Position the patient the same as for the mirror examination. All patients undergoing this procedure, in contrast to the mirror examination, must be topically anesthetized with an aerosolized local anesthetic agent as described above. Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, to provide better contrast.

Instruct the patient to protrude their tongue and to grasp it with a gauze square (**Figure 206-6**). Hold the eyepiece of the scope in the dominant hand. Use the dominant thumb to manipulate the tip controller. Grasp and hold the middle portion of the fiberoptic scope with the thumb and index finger of the nondominant hand. Brace the remaining fingers of the nondominant hand against the patient's face (**Figure 206-6**). Instruct the patient to breathe slowly through their mouth in a "panting-like" manner.

Advance the scope with both hands until the tip is situated within the middle of the mouth and over the base of the tongue. Use the hand control to direct the tip of the scope downward. Look through the scope and visualize the base of the tongue, the vallecula, and the tip of the epiglottis. Direct the scope posteriorly over the epiglottis. The larynx and hypopharynx will come into view (**Figure 206-3**). Adjust the eyepiece, if necessary, to focus the scope. **Avoid touching the epiglottis as this may induce gagging.** Entry into the laryngeal vestibule will allow a more detailed examination but may also induce laryngospasm if the vocal cords are touched. Perform a systematic examination of the laryngeal and hypopharyngeal anatomy. Instruct the patient to say "e-e-e" while viewing abduction and adduction of the vocal cords.

PER-ORAL RIGID FIBEROPTIC LARYNGOSCOPY

Position the patient the same as for the mirror examination. All patients undergoing this procedure, in contrast to the mirror examination, must be topically anesthetized with an aerosolized local anesthetic agent as described above. Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, or dim them to provide better contrast. Apply antifog solution onto the laryngoscope lens.

Instruct the patient to protrude their tongue. Either the patient or the examiner may grasp the patient's tongue with gauze as it

FIGURE 206-6. Positioning for an oral flexible fiberoptic examination of the larynx. The patient grasps their tongue with a gauze square. The examiner's left hand is braced against the patient's face.

FIGURE 206-7. Positioning for a rigid telescopic examination of the larynx. Note that the telescope is stabilized on the left thumb and the left fifth finger braces against the patient's face.

protrudes (**Figure 206-7**). Hold the scope with both hands while stabilizing the nondominant hand against the patient's face if the patient holds their own tongue. Hold the scope with the dominant index finger and thumb if the examiner is grasping the patient's tongue (**Figure 206-7**). Stabilize the scope with the dominant fifth finger against the patient's face. Instruct the patient to breathe slowly through their mouth in a "panting-like" manner.

Insert the laryngoscope into the center of the mouth. Advance it straight backward and over the tongue. Stop advancing the scope when the circumvallate papillae are reached. Instruct the patient to phonate as described above. Advance the scope until the larynx is visualized (**Figures 206-3 and 206-8**). Tilt and gently rotate the scope to visualize the entire larynx and hypopharynx during phonation and quiet breathing.

FLEXIBLE NASOPHARYNGOSCOPY OR NASOLARYNGOSCOPY

A relatively new technology for laryngeal visualization is the "chip-in-tip" laryngoscopes. Rather than fiberoptic cables, these flexible scopes have the video and lens apparatus at the tip of the scope and transmit the data to a processor. The processor converts the data into video images onto a screen. This scope produces a picture that

FIGURE 206-8. Endoscopic view of the larynx through a rigid 90° telescope.

is significantly brighter and less distorted (**Figure 206-1B**). It is an excellent tool for teaching and in children.⁷ However, the cost for a complete digital unit is three to four times the cost of a traditional fiberoptic laryngoscope.

Patient positioning is not crucial with this technique. Anesthetize the nasal passage if deemed necessary so that the procedure is best tolerated. Visualize both nasal cavities with a nasal speculum to determine which nasal passageway will be easier to pass the scope through. Decongest the nasal mucosa with aerosolized oxymetazoline, 3% ephedrine, or cocaine. Instruct the patient to sniff in deeply after the spray is applied. Allow 3 to 5 minutes to pass for the vasoconstriction to occur. Apply a topical anesthetic spray to the nasal passageway. Spraying achieves excellent vasoconstriction and anesthesia as the agents diffuse through the entire nasal cavity and pharynx. Alternatively, place cocaine or lidocaine with oxymetazoline-soaked pledgets into the nasal cavity inferior and superior to the inferior turbinate for 10 minutes to achieve excellent anesthesia and vasoconstriction.

Connect the light source to the fiberoptic scope and turn it on. Turn off the overhead room lights, if possible, to provide better contrast. Apply water-soluble lubricant onto the fiberoptic cord. **Do not get the lubricant on the lens or it will blur visualization.** Hold the eyepiece of the scope in the dominant hand (**Figure 206-9**). Use the dominant thumb to manipulate the tip controller. Grasp and hold the middle portion of the fiberoptic scope with the thumb and index finger of the nondominant hand. Brace the remaining fingers of the nondominant hand against the patient's cheek (**Figure 206-9**).

Insert the tip of the scope into the nose. Check both nasal airways with the scope minimally advanced in the nostril to see which side has a more patent airway and will thus allow an easier exam. Advance the scope in the easier nostril with both hands and directed either along the floor of the nose or along the superomedial aspect of the inferior turbinate depending upon the nasal anatomy (**Figure 206-10**). Instruct the patient to breathe through their nose as the nasopharynx is encountered. This lowers the soft palate and opens the nasopharynx. Direct the tip of the endoscope downward and advance it past the oropharynx. Slide the tip of the scope behind the epiglottis, along the posterior pharyngeal wall, and into the hypopharynx and larynx. **Avoid touching the epiglottis to prevent gagging and the vocal cords to prevent laryngospasm.** Almost all patients can tolerate this procedure. Gagging is unusual. Apply a topical anesthetic agent to the oral cavity and oropharynx if the patient gags. Perform a leisurely and thorough examination of the airway. **This is the only laryngoscopy technique in which normal speech can be observed.**

FIGURE 206-9. Positioning for a nasal flexible fiberoptic examination of the larynx. Note that the left, nondominant, hand is stabilized against the patient's face.

FIGURE 206-10. Anatomy of the lateral nasal wall and the two routes that the flexible scope can follow to gain access to the nasopharynx and subsequently the larynx.

ALTERNATIVE TECHNIQUES

The Emergency Physician must be looking through the rigid or flexible scope during the procedure. This in combination with holding, stabilizing, and advancing the scope makes fiberoptic laryngoscopy awkward if the Emergency Physician does not have much experience with this technique. An alternative, if available, is to connect the scope to a portable monitor (**Figure 206-11**). This makes the procedure less cumbersome and easier to perform. This type of setup is especially helpful in training situations (e.g., medical students, residents, and midlevel providers) as well as educating the patient and their family to the examination findings. A final alternative is to use a video laryngoscope (Chapter 20) to examine the airway.^{8,9} The Emergency Physician is usually more familiar with the video laryngoscope than the flexible or the 90° scopes.

AFTERCARE

Inform the patient that the effects of the topical anesthetic persist an average of 30 to 45 minutes. Alert the patient that they may experience symptoms of aspiration, such as coughing or choking, when swallowing. Liquids are more likely to cause problems than solids.

FIGURE 206-11. Nasopharyngoscopy using an external monitor for visualization of endoscopic images.

Instruct the patient not to ingest any solid or liquid substances until the topical anesthetic agent wears off. Mild bleeding from the scope abrading the mucosa is usually minimal and self-limited. The patient will need reassurance as rarely is any treatment required.

Scopes require cleaning and disinfection between uses. Gently wipe any blood, lubricant, mucus, and other body fluids off the scope. Disinfect the scope per the manufacturer's recommendations and hospital guidelines.

COMPLICATIONS

Few complications arise from laryngoscopy. Epistaxis is possible with nasal endoscopy. It is uncommon when using vasoconstrictive agents and careful manipulation of the scope. Emesis is rare, even in the patient with an extremely sensitive gag reflex. Laryngospasm can be avoided as long as care is taken to avoid direct contact with the vocal cords. Although rare, the patient can have an adverse reaction to the local anesthetic agent or the decongestant. These should be evaluated and managed similar to any other allergic reaction.

Aspiration during or after the procedure is extremely rare. Aspiration can be minimized by performing laryngoscopy on patients with an empty stomach, although this is often impractical in the Emergency Department.

Other complications are minor and result from mechanical trauma. The tip of the scope can rub against and abrade the mucosa. This can result in mild irritation, rhinorrhea, and hemorrhage. Inappropriate technique or patient movement during the procedure can result in mucosal lacerations.

SUMMARY

Visualization of the larynx is a basic and often a crucial component in the physical examination of the patient. A variety of techniques have been described, all of which are adequate in evaluating the larynx and hypopharynx. Risks and complications are rare. Maintain a very low threshold when deciding whether or not to perform laryngoscopy. Patient education and preparation are as important, if not more important, than equipment and instrumentation in obtaining a thorough examination.

Airway Foreign Body Removal

Guy Shochat, Jacqueline Nemer, David L. Walner, and Martin E. Anderson, Jr.

INTRODUCTION

The presence of an airway foreign body is a common cause of morbidity and mortality in children, especially those younger than 3 years of age. Children use their mouths to explore their surroundings. Over 70% of foreign body aspirations occur in children.^{1,2} Boys are twice as likely as girls to experience an airway foreign body.³ The incidence of airway foreign bodies has decreased over the past four decades due to public awareness campaigns. The mortality rate following foreign body aspiration is estimated to be 1% to 2%. This rate has remained fairly constant since the beginning of the 20th century. The mortality rate was approximately 24% prior to the advent of endoscopic techniques for airway foreign body removal.⁴ In the year 2000, ingestion or aspiration of a foreign body resulted in more than 17,000 Emergency Department (ED) visits in the United States.⁵ The death rate has remained at approximately 4000 deaths per year for the past two decades.⁶⁻⁸ **The most serious and life-threatening scenario is complete airway obstruction. This usually occurs at the level of the larynx or trachea.**

Common airway foreign bodies are food items, coins, jewelry, and toys. Food objects have been associated with 41% of deaths and nonfood substances have been associated with 59% of reported deaths.⁵ The leading causes of food foreign body airway obstruction are hard candy and nuts.^{5,9} Other globular objects such as hot dogs, soft candies, chewing gum, and grapes are commonly aspirated food objects.¹⁰ Coins and toys are commonly aspirated nonfood objects.^{5,9,11-13} Rubber balloons, jewelry, and toys are the most commonly aspirated nonfood objects.^{12,14} Vegetable matter accounts for 55% to 95% of airway foreign bodies, with nuts accounting for around 39% alone.¹⁵

Parents and caregivers should be educated and aware of the types of food and objects that pose a choking risk for children.^{12,16-18} They should become familiar with the methods to reduce this risk. All parents and caregivers should learn the techniques to treat a choking child. Basic life support classes are often available free or at a minimal cost at hospitals, churches, and community centers.

The management of airway foreign bodies in the hospital requires an emergency specialist capable of managing acute airway compromise. Airway foreign bodies located in the larynx, trachea, or pulmonary tree require an Otolaryngologist, Pulmonologist, or other qualified specialist with experience in airway endoscopy and the availability of that equipment in the Operating Room or an Intensive Care Unit. Cases involving children require specialized expertise and equipment for pediatric airway endoscopy. **The ED must manage the airway foreign body if the airway becomes unstable or if the consultants are not immediately available.** The morbidity and mortality associated with airway foreign body retrieval have greatly declined due to the development of safe endoscopic techniques, rod-lens telescopes, and optical forceps.

The burden of proof lies with the Emergency Physician (EP) to diagnose an airway foreign body. Diagnosis of an airway foreign body can range from the obvious to very difficult and unexpected. This diagnosis may be challenging because information gained from the history, physical examination, and radiologic studies may not clearly confirm the presence of an airway foreign body.^{11,19-23} An airway foreign body may not even be initially suspected in some cases. This is especially true in young children, patients with intoxication,

or patients with cognitive dysfunction. Physical examination and radiographic studies may appear normal. In some cases, the only definitive test will be endoscopy to evaluate the entire laryngo-tracheobronchial tree. **Many airway foreign bodies are neither observed nor suspected.**

The EP must often rely on clinical suspicion guided by knowledge of the epidemiology of airway foreign bodies.^{22,23} A choking crisis is the most sensitive clinical parameter of an airway foreign body. Coughing, choking, gagging, and throat clearing are reflexes designed to protect the airway.^{20,24} These signs indicate that an airway obstruction is incomplete. Complete airway obstruction is evident by sudden respiratory distress followed by the inability to speak or cough.

The physical examination may be normal in up to 39% of patients. Radiographic studies may be normal in up to 20% of the patients. **The only definitive test when considering the diagnosis of an airway foreign body is endoscopy to evaluate the entire laryngo-tracheobronchial tree.** This chapter reviews airway foreign body removal with an emphasis on foreign bodies located within the trachea or lower airway. Refer to Chapter 224 for a discussion regarding upper airway foreign bodies.

ANATOMY AND PATHOPHYSIOLOGY

The airway is divided into three anatomic regions: the larynx, the trachea, and the bronchi. The laryngeal aditus is formed by the epiglottis anteriorly, the aryepiglottic folds laterally and posteriorly by the corniculate cartilages and upper border of the arytenoid muscle. The larynx extends from the level of the aditus to the lower border of the cricoid cartilage where it is continuous with the trachea.^{9,11,19,25} The infant larynx is located higher in the neck than the adult larynx. The cricoid cartilage descends in the neck through childhood and is the narrowest part of the infant airway. The epiglottis is located with the tip often resting on the soft palate due to the superior position of the infant larynx.^{19,20,26} The infant larynx is approximately one-third the size of the adult larynx. Laryngeal foreign bodies are most common in infants due to the small size of the inlet and subglottis. Refer to Chapter 9 for a more complete discussion regarding the differences between the child and adult larynx.

It is important to be familiar with the anatomy of the pediatric and adult airway.¹⁹ The trachea begins at the lower border of the cricoid cartilage, extending downward from about the level of the sixth cervical vertebra in adults or the fourth cervical vertebra in infants. The trachea extends inferiorly to the level of the carina. The inferior end of the trachea is located at the level of the fifth thoracic vertebra or the sternal angle. The trachea is 4 cm long in a full-term newborn infant and 11 to 13 cm long in an adult. The diameter of the trachea is 3.6 mm in a newborn and 12 to 23 mm in an adult.²⁷

The trachea divides into two mainstem bronchi.²⁷ The right mainstem bronchus is shorter, straighter, and larger in diameter than the left mainstem bronchus. **This explains why right mainstem foreign bodies are more common than left mainstem foreign bodies.** The mainstem bronchi divide into three lobar bronchi on the right and two on the left. The lobar bronchi divide into segmental bronchi. There are 10 segmental bronchi on the right and 8 on the left.²⁷

The anatomic location of airway foreign bodies in pediatric patients varies by age.^{9,20,24,25} Airway foreign bodies commonly become lodged in the larynx, the trachea, or the bronchi. Laryngeal foreign bodies account for 4% to 5% of airway foreign bodies.²⁴ Laryngeal foreign body has a high mortality rate due to complete airway obstruction.^{28,29} Many survivors of transient airway obstruction suffer from hypoxic encephalopathy.

Most choking victims are able to generate a forceful cough to expel an airway foreign body. Some patients are unable to relieve the

obstruction themselves. The use of the Heimlich maneuver has further decreased mortality.³⁰ **It should be emphasized that the relief of an airway obstruction should only be attempted if signs of a complete airway obstruction are observed. The American Heart Association since 2005 no longer advocates blind finger sweeps as they may further impact foreign bodies into the larynx or esophagus.³¹ Only perform oral cavity finger sweeps if a foreign body is seen within the oral cavity.³² Immediate intervention is unnecessary and potentially dangerous if a patient is able to breathe, speak, or cough.³³**

A

B

Laryngeal foreign bodies can present with only mild or moderate respiratory distress. They may be located, or wedged, between the laryngeal ventricles, the true vocal folds, or the immediate subglottis (**Figure 207-1A**). Plain radiographs of the neck will detect radiopaque foreign bodies (**Figures 207-1B and 207-1C**). Flexible awake fiberoptic laryngoscopy allows visualization of the larynx and supraglottic structures.

Tracheal foreign bodies account for 9% and bronchial foreign bodies account for 81% of airway foreign bodies.³⁴ The “classic” diagnostic

C

FIGURE 207-1. Laryngeal foreign body. **A.** Coin lodged within the laryngeal ventricles resulting in a partial airway obstruction. **B.** Anteroposterior neck radiograph. **C.** Lateral neck radiograph.

triad of a tracheobronchial foreign body consists of the sudden onset of paroxysmal coughing, wheezing, and unilateral diminished breath sounds on the affected side.^{20,24} However, these symptoms may only be present in approximately half of cases. Approximately 33% of airway foreign bodies do not demonstrate any coughing, choking, or wheezing.³⁵ Tracheal foreign bodies may present with audible biphasic or expiratory stridor. Audible expiratory wheezing is more likely associated with a main bronchus obstruction. Tachypnea and cyanotic episodes may occur when larger obstructing objects are present. Small foreign bodies may travel distally to a secondary bronchus and produce the more subtle symptoms of mild wheezing, cough, pneumonia, or fever. No abnormalities are found in up to 39% of patients.³⁶ It is estimated that only 70% of patients with a foreign body aspiration seek treatment within the first week of the aspiration.^{29,37} Long-standing airway foreign bodies are associated with a considerable increase in morbidity. Early diagnosis is the key to successful management and risk reduction.¹

The most common airway foreign bodies are food items and toys. Peanuts account for nearly 39% of tracheobronchial foreign bodies (Figure 207-2).³⁸ Other common foreign bodies include plastic

A

B

FIGURE 207-2. Endoscopic view of a peanut in the right mainstem bronchus. **A.** Endoscopic view from just superior to the carina. Note that both mainstem bronchi are visible. **B.** Close-up view of the foreign body.

FIGURE 207-3. Chest radiograph of a patient with a left mainstem bronchus foreign body and a check valve-type of obstruction. Marks delineate the trachea and the mainstem bronchi.

toys, pins, tacks, watermelon seeds, sunflower seeds, nails, screws, carrots, and popcorn. More than 80% of airway foreign bodies are radiolucent and can be difficult to diagnose.^{20,39,40}

The most common radiologic findings are identified using both inspiratory and expiratory chest radiographs.⁴¹ The acute airway foreign body can be in the form of a check valve with postobstructive hyperinflation and mediastinal shift to the contralateral side (Figure 207-3). Inspiratory and expiratory chest radiography may identify a ball valve phenomenon with atelectasis, collapse of the distal airways, and mediastinal shift to the ipsilateral side with chronic foreign bodies. Lateral decubitus films are often used as an adjunct imaging study as young children are not often able to cooperate for inspiratory and expiratory chest radiographs. The lateral decubitus radiograph uses the patient's body weight to promote expiratory excursion. The use of decubitus films is no better than the use of upright films.⁴² The foreign body can be in the mainstem bronchus (Figure 207-4). Pneumonia can be present when the foreign body has been present for weeks or months. Chest radiographs can be normal in up to 20% of patients with tracheobronchial foreign bodies.^{11,20,24,25}

INDICATIONS

The indications for airway endoscopy must take into account the patient's history, physical examination, radiologic findings, and the suspected location of the foreign body. An accurate history is of

A

B

FIGURE 207-4. Chest radiograph of a patient with a right mainstem bronchus foreign body. **A.** Posteroanterior view. **B.** Lateral view. (Courtesy of www.lifeinthefastlane.com.)

the utmost importance in the diagnosis of foreign body aspiration as the remainder of the assessment, physical examination, and radiographic studies can be deceptively unremarkable.^{39,43} Many aspiration events are unwitnessed. The characteristic history consists of

an incipient choking or gagging episode. Caretakers often describe subsequent coughing spells when the event was witnessed. Aspiration must be assumed if the patient was eating peanuts, seeds, or beans during the episode. All witnessed aspirations with nuts or nondissolvable food matter require endoscopy and removal if the foreign material is identified.

The EP must have a high index of suspicion for an airway foreign body based upon history, physical examination, and radiologic findings.^{9,20} **However, the diagnosis is not always clear cut.²¹ It is the responsibility of the EP to suspect an airway foreign body.** Consult with the appropriate specialist and strongly suggest endoscopy consisting of laryngoscopy and/or bronchoscopy. Endoscopy remains the gold standard to manage or rule out an airway foreign body.^{24,39,43}

CONTRAINDICATIONS

The majority of patients presenting to the ED with airway foreign bodies are in stable condition. This allows time to adequately assess the patient and formulate the best possible treatment plan. Infants and children with airway foreign bodies require an institution with the capability for comprehensive pediatric care. This includes a physician who is experienced with airway endoscopy and foreign body retrieval in children and a facility with pediatric endoscopic equipment, pediatric anesthesia capabilities, and pediatric intensive care capabilities. This often will require transfer to a specialized pediatric center. **Attempting removal of airway foreign bodies in a less-than-adequate environment can be catastrophic for the patient and is not advised.** This same philosophy applies to adult airway endoscopy and to having qualified personnel who are experienced in this area.

Follow basic life support protocols in the case of an acutely obstructed airway and prepare to manage the airway if needed.^{44,45} A patient with a suspected laryngeal foreign body and a concern for impending airway obstruction should be closely observed and monitored while facilitating emergent endoscopy and control of the airway in the Operating Room. If urgent endoscopy is not available, direct laryngoscopy in the ED and removal of a visualized foreign body with a forceps (e.g., Magill, Boedeker, or Tylke) can be attempted. Options include plain radiographs to attempt to localize and assess radiopaque objects and fiberoptic or direct laryngoscopy by the EP if impending airway obstruction does not appear to be an issue and a laryngeal foreign body is suspected.^{24,43} A cricothyrotomy or percutaneous transtracheal jet ventilation may be required in an unstable patient with a laryngeal foreign body if attempts at resuscitation and/or removal are unsuccessful. **These two procedures are unlikely to be beneficial if the foreign body is located in the distal trachea or bronchi.**

The EP may attempt a lifesaving temporizing measure to dislodge the total airway obstruction distally if urgent endoscopy is not available. This lifesaving temporizing measure is orotracheal intubation. The endotracheal tube can be advanced as deeply as it will go or a bougie can be placed through the endotracheal tube and advanced to force the foreign body deeper into a mainstem bronchus. A flexible fiberoptic scope can be used to position the endotracheal tube into the contralateral mainstem bronchi. This mainstem positioning can be helpful in the case of a contralateral mainstem bronchus obstruction. A final alternative is the application of extracorporeal membrane oxygenation (Chapter 73).

EQUIPMENT

ED EQUIPMENT

- Intubation equipment
- Percutaneous transtracheal jet ventilator

- Cricothyroidotomy kit
- Suction source, tubing, and catheter
- Magill, Boedeker, or Tylke forceps (**Figure 29-2**)
- Laryngoscope with a variety of blades or a video laryngoscope
- Topical anesthetic
- Atomizer for topical anesthetic
- Fiberoptic nasopharyngoscope

Atomizer devices are usually not available in the ED. Many devices are available commercially. These are disposable devices that are single patient use (**Figure 29-1 and Table 29-1**). A Popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

An airway forceps is used to remove an airway foreign body. The Magill forceps is the standard used by most institutions (**Figure 29-2A**). It is available in infant, child, and adult sizes. The forceps tips twin blades for gripping are offset with serrated tips. It is curved at an oblique angle between the handles and the blades to prevent the view of the patient's airway from being obscured. The ends of the blades are rounded to minimize trauma. The Boedeker forceps (Karl Storz Endoscopy, El Segundo, CA) is an alternative to the Magill forceps (**Figure 29-2B**).⁴⁶ It is also curved but does not put the working end into the view of the intubator. The Tylke forceps (Rodinia LLC, Jupiter, FL) is a new device that is simple to use, safe, and an effective alternative to the Magill forceps (**Figure 29-2C**). The twist and bend of the Tylke forceps prevents visual obstruction and provides improved access to the trachea. It is available in three sizes (i.e., adult, adolescent, and child).

■ OPERATING ROOM EQUIPMENT

The proper equipment must be selected based upon the patient's age, the patient's size, and the suspected composition of the foreign body. Laryngoscopes are selected to allow visualization of the larynx and the passage of a bronchoscope. Rigid ventilating bronchoscopes with fiberoptic telescopes provide optimal visualization. This allows direct access to the airway, excellent visualization, continuous administration of an anesthetic agent and oxygen, and a conduit for the introduction of instruments (e.g., forceps) to retrieve the foreign object. Multiple sizes of laryngoscopes and bronchoscopes are essential to have available in the Operating Room. Numerous extraction instruments of different sizes and shapes must be available and include smooth, toothed, cupped, angled, open mouth, and optical forceps. The optical forceps allow a magnified and direct view through the forceps improving visualization and ease of foreign body removal.

PATIENT PREPARATION

Timing of endoscopy and airway foreign body retrieval must be based upon each individual patient. **Do not waste time if impending airway obstruction exists.** Immediately notify and mobilize an Anesthesiologist, Otolaryngologist, and the Operating Room as this is an emergent situation. It is appropriate to wait for NPO (nothing by mouth) status to be present and the stomach to empty prior to proceeding to the Operating Room if the diagnosis of an airway foreign body is highly suspected and the patient is stable. This is considered a timely approach and may take up to 6 hours for children or 8 hours for adults. Waiting this time in the stable patient decreases the risk of aspiration and further compromising the situation. It is also appropriate to wait in a stable patient to assemble the appropriate and best nursing and anesthesia team to care for the patient. Using personnel who are unfamiliar with endoscopy can create a compromised and stressful situation.

TECHNIQUES

ED TECHNIQUES

The foreign body airway obstruction protocol based upon Pediatric Basic Life Support treats conscious infants younger than 1 year of age with four back blows while the infant is in a prone position on the rescuer's forearm, face down, and their head lower than their trunk.^{37,47,48} This is combined with four rapid chest thrusts, if the obstruction persists, while the infant is supine with their head lower than their body.^{32,44} Treat unconscious infants by opening the airway and attempting rescue breathing based on basic life support protocols.^{32,44} Treat children older than 1 year of age and adults with the standard Heimlich maneuver. **Use gentle thrusts in smaller children to decrease the likelihood of injury to the abdominal organs.**^{44,49} **Finger sweeps to remove a foreign body in the oral cavity should only be performed if the foreign body is directly visualized. Blind finger sweeps are not recommended as they can further impact the foreign body and obstruct the airway.**^{44,45} Refer to Chapter 224 for more information on relief of choking and acute airway foreign body removal.

The Heimlich maneuver can be a lifesaving procedure but it is also associated with a wide range of serious complications. Reported Heimlich complications include solid organ injury to the liver, spleen, and pancreas; perforation of the esophagus or stomach; diaphragmatic rupture; fracture of sternum, ribs, or vertebra; hemothorax; pneumothorax; or a pulmonary contusion.^{30,49-52} Any patient who is symptomatic following the Heimlich maneuver must be thoroughly evaluated and closely observed for potential complications.

It is always best not to manipulate the airway or attempt intubation in a stable patient with an airway foreign body and who is moving air and breathing. The airway is best controlled in the Operating Room at the time of the actual foreign body removal. Once the airway is manipulated a foreign body can become dislodged, turning a partial airway obstruction into a complete airway obstruction. If this occurs in the Operating Room, the bronchoscopy equipment is available for urgent use by the Endoscopist.

Attempt orotracheal intubation in the ED if the airway obstruction progresses rapidly and the patient cannot be ventilated. Proceed to direct or video laryngoscopy. Intubation can be used to force the foreign body into one mainstem bronchus and allow ventilation of the other lung. One-lung ventilation will keep the patient alive until the foreign body can be removed in the Operating Room. Position the laryngoscope to visualize the larynx. Grasp the foreign body with a forceps (e.g., Magill, Boedeker, or Tylke) and remove it if a foreign body is visualized. Intubate the patient if no foreign body is visualized. Insert and advance the endotracheal tube as far as it will advance distally if the foreign body is not visualized or unable to be grasped. Attempt to pass a smaller endotracheal tube if the original endotracheal tube will not pass. Withdraw and position the endotracheal tube with the tip above the carina to optimize ventilation. As an alternative, insert and position the endotracheal tube above the carina and then advance a bougie through the endotracheal tube in an attempt to move the foreign body distally.

Always be prepared to perform a cricothyrotomy or transtracheal jet ventilation. Transtracheal jet ventilation allows for short-term oxygenation, is temporary, and may allow time for safe transport to the Operating Room so that endoscopy and foreign body retrieval can be performed in a more controlled environment with appropriate equipment at hand. Refer to Chapters 18, 32, and 31 regarding the details of orotracheal intubation, cricothyroidotomy, and transtracheal jet ventilation, respectively.

Direct laryngoscopy and bronchoscopy in a child or adult with an airway foreign body is a dangerous situation. The procedure

may result in a partial airway obstruction becoming a complete airway obstruction. **Always have a cricothyroidotomy tray immediately available.** All equipment must be selected, assembled, and ready for use.

It is possible to remove foreign bodies located within the hypopharynx in the ED. Typical foreign bodies that may be removed include pieces of food and bones. **The patient must be stable and in no risk of airway compromise.** Obtain anteroposterior and lateral soft tissue radiographs of the neck to localize, if possible, the foreign body. There has been an increase in the use of computed tomography (CT) scans to attempt to identify potential fish or chicken bones that may be lodged in the pharynx, hypopharynx, or esophagus in the stable patient. The CT scan is superior to plain radiographs but the use needs to be weighed against the risk of radiation exposure. Perform a laryngoscopy (Chapter 206) or awake direct intubation to identify the foreign body and its location.

Place the patient in full monitoring (e.g., pulse oximeter, cardiac monitor, and noninvasive blood pressure cuff). Apply a topical anesthetic spray to the oropharynx and the base of the tongue. Alternatively or additionally, administer a nebulized local anesthetic (e.g., 5 mL of lidocaine 2% in a standard nebulizer unit). **Avoid Cetacaine spray due to concerns of methemoglobinemia from the benzocaine.** Administer a small dose of an intravenous sedative if required.

Place the patient supine. Slowly and gently insert the laryngoscope blade. An alternative to a traditional laryngoscope, if available, is a video laryngoscope. The video laryngoscope may provide a better field of view with less manipulation. **Do not immediately insert the laryngoscope blade all the way.** Stop frequently to lift the laryngoscope and look for the foreign body. This slow insertion and frequent looks will prevent the laryngoscope blade from pushing the foreign body further into the airway. Elevate the patient's tongue and jaw. Grasp the foreign body with a forceps (e.g., Magill, Boedeker, or Tylke) if it is visualized. Withdraw the forceps followed by the laryngoscope.

OPERATING ROOM TECHNIQUES

The procedure begins with the induction of general anesthesia. It cannot be overemphasized that anesthesia should only be administered by an Anesthesiologist who is competent and comfortable with the situation. Pediatric patients require an Anesthesiologist with pediatric airway experience. Full monitoring and mask induction allow the patient to maintain spontaneous respiration. Muscle relaxants are avoided as they can induce complete airway obstruction.

The Otolaryngologist begins the procedure. Place the patient supine with a shoulder roll to position the airway. Insert the laryngoscope into the larynx. Expose the larynx by elevating the laryngoscope. Topical anesthetic is applied to the larynx to avoid laryngospasm. The bronchoscope with a telescope is then passed under direct vision through the mouth and into the laryngeal introitus. Ventilation can continue via a port on the scope. The foreign body is visualized. Forceps are inserted through the scope and used to grasp the foreign body. Small objects can be removed directly through the scope whereas larger objects require simultaneously removing the bronchoscope along with the forceps and foreign body. The bronchoscope is passed again after the removal of the foreign body to identify any mucosal injury or a second foreign body which may occur in as many as 5% of patients.³⁶ A culture may be obtained and antibiotics administered if purulent secretions are noted.

A specific type of foreign body (e.g., a tack or sharp object) may become lodged in the larynx or upper trachea. Extraction with the forceps using standard endoscopic techniques may not be possible. Patients may require a tracheotomy and an open approach (e.g., a laryngotomy) to remove the foreign body.³³ A distal airway foreign

body that cannot be removed may require a thoracotomy but this incurs a significant increase in surgical morbidity.

ALTERNATIVE TECHNIQUE

The use of a flexible fiberoptic bronchoscope to retrieve bronchial foreign bodies may be acceptable for EPs who are well trained with this technique. The mainstay of tracheobronchial foreign body retrieval remains rigid bronchoscopy.

AFTERCARE

Most patients should be breathing spontaneously after the retrieval of an airway foreign body. An endotracheal tube may rarely (e.g., in the presence of significant laryngeal or tracheobronchial edema) need to remain in place. This would require admission to an Intensive Care Unit. Humidified oxygen is helpful to keep the airway moist and prevent mucous crusts from forming. A postprocedural radiograph will help to determine any subcutaneous emphysema, pneumomediastinum or pneumothorax, or any changes to the lung fields following the extraction.

All patients who have undergone foreign body removal require at least a few hours of airway observation in a monitored setting. Racemic epinephrine treatments, Heliox, and/or intravenous dexamethasone can be administered as adjunctive therapies. Discharge from the hospital is acceptable when the patient is breathing comfortably and no longer in danger of airway compromise.⁵⁴ Some patients may be discharged home the same day while others may require multiple days of airway support and observation. Educate parents and caregivers about the prevention of foreign body aspiration.^{12,16-18}

Granulation tissue, severe inflammation, and a pneumonia can form around the foreign body making removal difficult or impossible when a bronchial foreign body has been present for a prolonged period of time.⁵⁵ It may be necessary to treat the patient with intravenous steroids and antibiotics for 48 hours, with or without intubation, followed by a repeat bronchoscopy and a repeat attempt to remove the foreign body.

COMPLICATIONS

Complications from the foreign bodies themselves (e.g., a button battery) or attempts at their retrieval can potentially lead to hypoxia or cerebral anoxia. Intraoperative complications can occur in the hands of both experienced and inexperienced Endoscopists. Loss of control of the foreign body can turn a partially obstructed foreign body into a completely obstructive foreign body and lead to a respiratory arrest. Cardiac arrhythmias can occur from hypoxia or direct pressure on the left mainstem bronchus. Bradycardia may also result from stimulating the trachea or from prolonged hypoxia. Postoperative problems can include laryngeal or tracheobronchial edema from the foreign body or the instrumentation of the airway. Mucosal irritation can instigate a tracheitis or bronchitis. Pneumonia can develop. Pneumomediastinum has been reported in up to 13% of aspirations and a pneumothorax slightly less frequently.⁵⁶

A foreign body pulled up from a mainstem bronchus can become dislodged in the larynx or trachea and cause a complete airway obstruction. A foreign body in the hypopharynx can be pushed distally into the airway and result in a total airway obstruction or can be pushed distally into the esophagus causing obstruction of the esophagus and anterior displacement of the membranous trachea. The foreign body needs to be quickly removed or pushed back down into one of the mainstem bronchi to allow ventilation of at least one lung or a surgical airway needs to be performed. Failure to react appropriately in this situation can result in asphyxiation and death.

FUTURE CONSIDERATIONS

A three-pronged instrument has been developed to grasp a round foreign body.⁵⁷ This may be used through a fiberoptic endoscope or freehanded in the ED. It was designed similar to devices available at the local hardware store. More research is needed before this device may be used in the ED.

SUMMARY

Airway foreign bodies can pose a diagnostic and therapeutic challenge. The presentation may be obvious or require review of any historical fact, physical abnormality, or radiographic abnormality that may lead to a definitive or presumed diagnosis of an airway foreign body. Suspicion of the presence of a foreign body must be followed up with visualization of the airway in the ED or in the Operating Room. Transfer may be required for stable patients if the endoscopy team and equipment are not available, especially in the case of children. Hypopharyngeal foreign bodies may be safely removed in the ED by an EP. The EP must anticipate and be prepared to perform critical airway management if there is clinical degradation including complete airway obstruction. These airway skills include intubation, forcing the foreign body into a mainstem bronchus to facilitate temporary one lung ventilation, cricothyrotomy, and percutaneous transtracheal needle ventilation.

208 Peritonsillar Abscess Incision and Drainage

Daniel S. Morrison and Chirag N. Shah

INTRODUCTION

A peritonsillar abscess is the most common deep infection of the head and neck encountered in young adults in the Emergency Department.^{1,2} The incidence has remained stable in the United States at 30 cases per 100,000 people.³ The incidence in the United Kingdom has increased 18% over 10 years.^{3,4} This infection can occur in all age groups. It is relatively rare before the age of 5 years. The highest incidence occurs in teenagers and young adults, and incidence gradually declines after the age of 40.^{5,6} There is a female-to-male predominance until the age of 14.⁷ There remains controversy in the literature regarding the optimal antibiotic choice and the mechanism of drainage. The objective for the Emergency Physician remains to make an accurate diagnosis, to institute appropriate care, and to arrange timely follow-up.

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of oropharynx anatomy is imperative. The anatomy of the oral cavity is relatively simple (Figure 208-1). The peritonsillar abscess can be found posterolateral to the palatine tonsil and posterior to the palatoglossal fold (i.e., arch). **Note the close proximity of the internal carotid artery and the facial artery to the peritonsillar abscess (Figure 208-2).** Use extreme care to not penetrate too deeply and puncture or lacerate these arteries.

The duration of reported symptoms ranges from 2 to 7 days for patients with ultrasound (US)-proven peritonsillar abscesses.^{8,9} The most common symptoms include fever, sore throat, dysphagia, muffled voice (i.e., the “hot potato” voice), and trismus.¹⁰ Physical

FIGURE 208-1. Anatomy of the oropharynx as seen through the open mouth.

examination will reveal a nonexudative pharyngitis in the majority of cases, soft palate edema, a bulging prominent tonsil, and uvula deviation away from the abscessed tonsil (Figure 208-3). The differential diagnosis includes intratonsillar abscess, peritonsillar cellulitis, infectious mononucleosis, malignancy, leukemia, odontogenic infections, aberrant carotid arteries, internal carotid artery pseudoaneurysms, and aneurysms of the internal carotid artery. The frequency of bilateral peritonsillar abscesses has been reported to be between 1.9% and 24% with the unsuspected contralateral abscess being discovered during surgery for the acute abscess tonsillectomy.¹¹ The Emergency Physician should maintain a high index of suspicion even if uvular deviation is not noted.

Intraoral US for a peritonsillar abscess has been performed since the 1990s. It was first described in the Otolaryngology literature and subsequently in the Emergency Medicine literature. The first case series of patients whose peritonsillar abscesses were drained under US guidance was described by Blaivas and colleagues.¹² US guidance has been shown to have a high degree of sensitivity (85% to 92%) and specificity (80% to 100%).^{13,14} US offers the advantage of confirming the presence of an abscess prior to aspiration attempts, allowing visualization of important neighboring structures (e.g., the internal carotid artery), and using no ionizing radiation.¹⁵⁻¹⁹ Bedside US reduces the delay of consulting an Otolaryngologist, admission, and drainage of the abscess when compared to a computed tomography scan.²⁰ Some patients with a peritonsillar abscess may be misdiagnosed with cellulitis and not undergo drainage. The use of US can prevent this. Up to 24% of patients have false-negative results on blind aspiration because the peritonsillar abscess can be multilocular and its location can vary.^{13,21,22} US will identify the location of the abscess to limit the number of false-negative aspirations. US decreases the Otolaryngologist consult rate.²³ Transcutaneous US can be used to assist with the diagnosis of a peritonsillar abscess in patients in whom intraoral US may not be possible (e.g., pediatric population).²⁴⁻²⁶

The peritonsillar abscess has been attributed to progression and direct extension of an acute exudative pharyngitis. It has also been proposed that the Weber's glands located in the supratonsillar space are the actual site of bacterial invasion and subsequent abscess

FIGURE 208-2. Horizontal section through the mouth and oropharynx. Note the close proximity of the peritonsillar abscess to the internal carotid artery and the facial artery.

formation.²⁷⁻²⁹ The glands clear the tonsillar area of debris and assist with the digestion of food particles trapped in the tonsillar crypts. A local cellulitis can develop if the Weber's glands become inflamed.²⁸ The bacterial inoculum results in tissue necrosis and pus formation between the tonsillar capsule and the lateral pharyngeal wall and/or the supratonsillar space. Progression of pus formation and cellulitis within the supratonsillar space results in a gradual involvement of the surrounding musculature, particularly the internal pterygoids, and leads to muscle spasm and trismus.

Most peritonsillar abscesses are polymicrobial infections containing common oropharyngeal microflora with an average of three isolates per specimen.^{6,30,31} Group A streptococci and *Fusobacterium necrophorum* are the most commonly isolated organisms if the Weber's glands become inflamed.⁶ Pure cultures containing *Streptococcus milleri* group, *Staphylococcus aureus*, *Nocardia asteroides*, *Haemophilus influenzae*, *Arcanobacterium haemolyticum*, *Streptococcus pneumoniae*, and *Streptococcus pyogenes* have also been recorded.^{6,30} There can be a higher incidence of group A beta-hemolytic streptococci in the winter and spring compared to the summer.⁷ Patients aged 15 to 24 have a higher risk of peritonsillar abscess due to *Fusobacterium necrophorum*.^{7,31} Children up to 9 years of age are at increased risk of being affected by group A streptococci.^{7,31} There can be an increased prevalence of beta-lactamase-producing organisms.³²

Treatment options for a peritonsillar abscess have undergone a significant amount of debate in the literature. Most treatment guidelines recommend appropriate antibiotic selection and removal of purulent fluid. Techniques of fluid removal range from simple or single aspiration of the abscess to repeated aspirations to incision and drainage. Patients treated with aspiration alone have success rates ranging from 85% to 100%.³³⁻³⁵ The cure rates for simple aspiration versus incision and drainage are similar.³⁶⁻⁴⁰ The overall recurrence rate is less in patients undergoing incision and drainage.³³⁻³⁵ Patients with less severe symptoms and smaller abscesses may be

treated medically without significant outcomes from those treated with surgical intervention.⁴¹ A younger age, fewer episodes of acute tonsillitis, and small abscess pockets are significant predictors in the pediatric population of a good response to nonsurgical treatment.⁴² The response to nonsurgical treatment significantly deteriorates after 7.5 years of age.⁴²

INDICATIONS

Most peritonsillar abscesses require either aspiration or incision and drainage. **The gold standard to diagnose a peritonsillar abscess remains the collection of pus through needle aspiration or the identification of a peritonsillar fluid collection using US.** The decision regarding the drainage technique is left to the Emergency Physician's preference and, if needed, in consultation with an Otolaryngologist.

US may be used to confirm the presence of a peritonsillar abscess, to guide needle aspiration of a confirmed peritonsillar abscess, and/or rescue a failed blind needle aspiration. The use of US can confirm the presence of a cellulitis with no underlying abscess. It will also confirm that the "mass" is not an aberrant internal carotid artery.^{19,43} US can distinguish a simple peritonsillar abscess from more complex masses that may have parapharyngeal spread.⁴⁴

CONTRAINDICATIONS

There are no absolute contraindications to draining a peritonsillar abscess. Patients with severe trismus limiting visibility, limiting access, and limiting intraoral US may require intravenous analgesics and muscle relaxants, procedural sedation (Chapter 159), or intraoperative drainage. **Consult an Otolaryngologist for all patients who are coagulopathic, taking oral anticoagulants, or with a known bleeding disorder.** These patients are at risk for significant

bleeding and associated complications. Admit children to the hospital for intravenous antibiotics, possible incision and drainage under general anesthesia, and possible tonsillectomy. The procedure should be avoided in patients who are uncooperative, unable to follow instructions, unable to sit upright, and those who are very young to prevent iatrogenic complications.

EQUIPMENT

■ GENERAL SUPPLIES

- #11 scalpel blade on a handle
- Curved hemostat
- Frazier suction catheter
- Suction source and tubing
- Tongue depressors
- Topical anesthetic spray (e.g., Cetacaine, lidocaine, tetracaine, or benzocaine)
- Syringe, 3 or 5 mL
- 25 or 27 gauge needle, 2 inches long
- Local anesthetic solution with epinephrine
- 10 mL syringe
- 18 gauge needle
- Culturettes or culture bottles
- Headlamp or adjustable overhead light source
- Other light sources (e.g., a pelvic speculum or curved laryngoscope blade) can be used as options
- Gloves

FIGURE 208-4. Anesthesia techniques. **A.** Topical spray anesthesia. **B.** Infiltrative anesthesia.

- Face mask with an eye shield
- Gown
- Oral rinse solution (e.g., hydrogen peroxide or Peridex)

■ US GUIDANCE

- US machine
- High-frequency microconvex endocavitary or hockey-stick US transducer⁴⁵
- Sterile US gel
- US transducer cover

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Obtain an informed consent for the procedure and place this in the medical record. When performing the procedure on a neonate or child, it is advisable to give the parent the option to leave the room or look away as the procedure can be disconcerting to some parents. The discussion should include proximate structures as well as hand signals that should be used if the patient requests the procedure to be stopped once it starts. Ensure that the patient has a thorough understanding of the postprocedural care instructions and follow-up requirements.

Position the patient sitting in an upright multipositional procedure chair. Alternatively, place the patient sitting upright on a gurney with the back elevated. Prepare the wall suction unit to ensure it is working. Apply suction tubing and a suction catheter to the suction source. The Emergency Physician should wear gloves, a gown, and a face mask with eye protection. This protective wear will prevent against becoming exposed, contaminated with oral secretions, or contaminated with abscess contents during the procedure if the patient coughs.

The use of good lighting cannot be overemphasized. Apply a headlamp if one is available. An alternative is an overhead adjustable light source. Position the light so that it is aimed in the patient's mouth. The overhead light often hits the examiner in the head, casts shadows, is too bright for the patient's eyes, and is also difficult to properly position because both of the Emergency Physician's hands must be used for the procedure. An additional alternative is to use a vaginal speculum with a fiberoptic light source (**Figure 88-3F**). This may require an assistant to position and hold the speculum against the tongue and apply downward pressure. A further alternative is to use a curved laryngoscope blade to depress the tongue and provide adequate lighting.

Incision and drainage must be preceded by adequate anesthesia to the abscess site. Determine the most fluctuant region of the abscess. Anesthetize this area. Spray topical anesthetic over the abscess (**Figure 208-4A**). Dry the mucosa overlying the peritonsillar abscess with a gauze square. Arm a 3 mL syringe with a 25 or 27 gauge needle. Inject 1 mL of local anesthetic solution containing epinephrine through the area of topical anesthesia and just under the mucosal surface (**Figure 208-4B**). Allow 3 to 5 minutes for the anesthetic to work.

Atomizer devices are usually not available in the Emergency Department. Many devices are available commercially. These are disposable devices that are single patient use (**Figure 29-1** and **Table 29-1**). A Popular device is the MAD line of mucosal atomizer devices (LMA North America, San Diego, CA). They make multiple devices for all topical needs.

TECHNIQUES

ASPIRATION

Identify the area of maximal fluctuance at the upper pole of the abscess. Anesthetize the area as described previously. Prepare the equipment. Apply an 18 gauge needle onto a 10 mL syringe. **A smaller needle may not allow thick pus to be aspirated.** Break the bead of the syringe. Trim the needle cap and place it over the needle to act as a depth gauge (**Figure 208-5A**). The needle should project only 1 cm from the distal end of the needle cap. Alternatively, apply a piece of tape onto the needle to mark a point 1 cm from the tip of the needle (**Figure 208-5B**). **The guard cap or tape serves as a marker for the maximum allowable depth to insert the needle during the procedure. Limiting of the depth of insertion of the needle should help to prevent injury to the carotid artery.** The mean distance from the abscess to the mucosal surface can range from 6 to 15 mm and the distance from the wall of the abscess to the internal carotid artery can vary from 5 to 25 mm.⁴⁶

Depress the tongue with a tongue depressor held in the nondominant hand (**Figure 208-6A**). A pelvic speculum or curved laryngoscope blade may be used. Insert the prepared needle attached to the syringe into the upper pole of the abscess and into the point of maximal fluctuance (**Figures 208-6A and 208-6B**).^{36,39,47,48} Hold and advance the needle parallel to the floor and direct posteriorly. **Do not direct the needle laterally where it can injure the carotid artery.** Aspirate while advancing the needle. Approximately 70% to 90% of abscesses occur in the upper pole of the tonsil.^{9,36,39} Continue to aspirate and remove as much purulent material as possible

A

C

B

FIGURE 208-5. Safety techniques to prevent injury to the internal carotid artery. **A.** The needle cover is cut and placed over the needle as a guard. **B.** Tape applied to an 18 gauge needle. **C.** Tape applied to a #11 scalpel blade.

if purulent fluid is obtained. Consider obtaining a culture and sensitivity of the aspirated material. Allow the patient to rinse and spit several times with Peridex solution or half-strength hydrogen peroxide solution.

Reattempt the procedure if the initial aspirate is negative by inserting the needle into the middle pole and then the inferior pole of the abscessed tonsil until purulent material is obtained (**Figure 208-6A**). **A completely negative aspiration, while more consistent with a tonsillar cellulitis, does not rule out the existence of an abscess.** Gentle palpation will reveal fluctuance when an abscess is present.

Almost 89% of patients were successfully treated with a single aspiration.⁴⁹ Just over 11% needed an additional aspiration or an incision and drainage in the immediate short term. High fever was a predictor of the need for additional procedures.

INCISION AND DRAINAGE

It is recommended to always perform a needle aspiration prior to the incision and drainage technique. Aspiration will localize the collection of pus and allow a more accurate incision and drainage.

A

B

FIGURE 208-6. Needle aspiration of a peritonsillar abscess. **A.** Recommended sites for needle aspiration. **B.** Aspiration in the first area.

FIGURE 208-7. Incision and drainage of a peritonsillar abscess. **A.** The incision site is the same site for the first aspiration. **B.** Incision with a #11 scalpel blade. Note the tape marking the maximum insertion depth of the scalpel blade. Suction any bloody or purulent fluid that escapes from the incision. **C.** Hemostat gently inserted to break any loculations.

A negative aspiration at all three sites (Figure 208-6A) is a contraindication for an incision and drainage procedure. It may be too early and an abscess has not yet formed. A negative aspiration at all three sites suggests the patient has a tonsillar cellulitis requiring oral antibiotics, gargles with hydrogen peroxide, and follow-up in 24 hours for reevaluation.

Identify the area of maximal fluctuance at the upper pole of the abscess. Anesthetize the area as described previously. Prepare the equipment. Place a piece of tape on the #11 scalpel blade so that only 0.75 to 1 cm is exposed (**Figure 208-5C**). Place the Frazier suction catheter near the incision site. Insert the scalpel blade to make a horizontal stab wound to a maximum depth of 1 cm in the same area noted for the aspiration technique (**Figures 208-7A and 208-7B**). The Frazier suction catheter will remove any blood and purulent material and prevent the patient from aspirating. **The depth of the stab should be no more than 1 cm. Extend the length of the incision to a maximum of 1.0 to 1.5 cm.**

Insert a curved hemostat into the wound (**Figure 208-7C**). Gently spread apart the jaws of the hemostat to break up any loculations in the abscess. Continue to simultaneously suction the area during the procedure. Packing of the abscess cavity is not required. Obtain a culture and sensitivity of the purulent material. Allow the patient to rinse and spit several times with Peridex solution or half-strength

hydrogen peroxide solution. Leave the suction in the patient's hand so they can use it as needed.

ULTRASOUND GUIDANCE

US has the ability to identify the location of the abscess and prevent unnecessary "dry aspirations." The use of US should be strongly considered whenever available. Anesthetize the area as described previously. Prepare the equipment. Place sterile US gel on the scanning surface of the US transducer. Apply the US transducer cover. Take care to avoid trapping air bubbles between the cover and the US transducer as they can seriously degrade the image. Apply sterile US gel over the covered US transducer surface.

Gently insert the US transducer into the patient's oral cavity. Direct the US transducer to the peritonsillar area and until it rests lightly against the posterior pharynx (**Figure 208-8**). Maintain the US transducer in a transverse orientation to maximize visualization of the posterior pharynx. Note the location of the palatine tonsil, a small oval structure with low-level echoes, and the internal carotid artery (**Figure 208-9**). A peritonsillar abscess can have variable appearances on US. They usually are heterogeneous, cystic, and adjacent to the tonsil (**Figure 208-10**). The carotid artery usually lies 5 to 20 mm posterolateral to the tonsil. Note the depth and location of the abscess.

FIGURE 208-8. Placement of the endocavitary US transducer inside the oral cavity and directed against the peritonsillar area.

FIGURE 208-9. Transverse color Doppler scan of the normal posterior pharynx. The tonsil (T) is visible on the top of the image. The internal carotid artery is noted by its red color Doppler signal.

FIGURE 208-10. Intraoral ultrasound image. The needle (arrows) is inserted into the peritonsillar abscess (A). The tonsil (T) is visible on the top of the image. The internal carotid artery is not visualized in this image.

Confirm the presence of a peritonsillar abscess and map its location. Use the previously described techniques for aspiration or incision and drainage. Alternatively, perform a needle aspiration under real-time US guidance. Use the long axis approach to direct the needle into the peritonsillar abscess (**Figure 208-10**). Leave the suction in the patient's hand so they can use it as needed. Ensure the endocavitary transducer is cleansed per institutional guidelines.

ASSESSMENT

Aspiration or incision and drainage will result in significant relief of the patient's pain and trismus. Allow the patient to rinse and spit with either Peridex solution or half-strength peroxide solution. Observe the patient for any evidence of continued bleeding or upper airway symptomatology. Assess the patient's ability to tolerate oral fluids prior to discharge.

AFTERCARE

Discharge the patient with oral antibiotics and analgesics.^{50,51} Antibiotic resistance to clindamycin and erythromycin is common across streptococcal strains and staphylococcal strains.³¹ Penicillin resistance is common in staphylococcal strains responsible for a peritonsillar abscess.³¹ The emergence of beta-lactamase-producing organisms has to be considered in antibiotic selection.⁵² Many Otolaryngologists will add to the penicillin either clindamycin or metronidazole due to the increasing incidence of penicillin-resistant organisms.^{33,53} Penicillin or a cephalosporin plus metronidazole appears to be effective in vitro in 98% of isolates.⁵⁴ Nonsteroidal anti-inflammatory drugs (NSAIDs) should adequately control pain and fever. Administration of 3 mg/kg, to a maximum of 250 mg, of methylprednisolone intramuscularly has been shown to decrease pain and inflammation.⁵⁵ Alternatively, the use of a single dose of 10 mg of intravenous or intramuscular dexamethasone has been shown to reduce pain levels and improve patient quality of life at 24 hours.^{56,57}

Recommend to the patient to follow a soft diet and drink plenty of fluids during the first 48 hours after the intervention. Instruct the patient to gargle with half-strength hydrogen peroxide or Peridex after each meal, at a minimum, and several other times per day. Arrange follow-up within 48 hours. **The patient should follow-up sooner if they do not improve.** Instruct the patient to return to the Emergency Department immediately if they develop bleeding,

shortness of breath, difficulty swallowing, drooling, or have any concerns.

Admission is generally required for patients who appear toxic, pediatric patients, dehydrated patients, immunocompromised patients, patients with recurrent abscesses, and patients who are unable to tolerate oral fluids. These patients require observation for 23 hours and intravenous antibiotics. The abscess is often drained in the Operating Room by the Otolaryngologist.

Patients may develop recurrent peritonsillar abscesses. Predictors for recurrence include the need for a repeated procedure at the initial presentation, younger age, female sex, and patients known to have recurrent tonsillitis.^{49,58} Tonsillectomy has been shown to be curative for recurrence of peritonsillar abscess.⁴⁹

COMPLICATIONS

There are few complications associated with the management of a peritonsillar abscess. Potential complications include aspiration pneumonitis, airway obstruction, hemorrhage, or extension of infection into deep tissue of the neck. Aspiration pneumonitis or lung abscess can occur secondary to abscess rupture.²⁸ Protect against aspiration of purulent material and subsequent pulmonic infection by having the patient sit upright during the procedure and using suction as the abscess is opened. Making an incision that is too large or too deep can injure the carotid artery or a carotid artery aneurysm. This could result in prolonged bleeding or hemorrhage. Always limit the depth of the needle or scalpel insertion and strongly consider US guidance. Certain patients may be sensitive to topical anesthetic spray and develop methemoglobinemia.

The use of US to locate and assist in the drainage of a peritonsillar abscess is associated with several pitfalls. Failure to recognize the internal carotid artery can be catastrophic for the patient. Always note the relationship of the tonsil and the peritonsillar abscess to the internal carotid artery.⁸ The internal carotid artery lies posterolateral to the tonsil. The use of color Doppler can assist in the identification of the carotid artery and differentiate it from the peritonsillar abscess. US may fail to identify a peritonsillar abscess. Fluid within a peritonsillar abscess is usually hypoechoic. It can appear isoechoic or hyperechoic.

SUMMARY

A peritonsillar abscess is commonly encountered in the Emergency Department. Diagnosis and treatment result in rapid symptom resolution in the majority of patients. Admission may be required in a few instances for observation and intravenous antibiotics. Appropriate antibiotics after the procedure can prevent a recurrence of the peritonsillar abscess. The use of steroids in conjunction with appropriate drainage improves the patient's pain and quality of life.

Dental Anesthesia and Analgesia

Eric F. Reichman

INTRODUCTION

Dental anesthesia techniques are used by Emergency Physicians for a variety of intraoral and extraoral conditions. This includes dental caries, jaw fractures, dry sockets, intraoral hemorrhage, laceration repair, and tooth fractures. These techniques are simple to learn, easy to perform, and provide temporary pain relief for the patient. **The Emergency Physician can provide pain-free intraoral manipulations, extraoral manipulations, facial manipulations, and simple pain control until the patient receives definitive evaluation and treatment by a Dentist or Oral Surgeon.** The fundamental principles of dental anesthesia and anatomy will be discussed so that the Emergency Physician will feel knowledgeable and comfortable performing dental anesthetic techniques.

ANATOMY AND PATHOPHYSIOLOGY

An understanding of the anatomy of the fifth cranial nerve is essential to performing dental nerve blocks (**Figure 209-1**).¹⁻³ The fifth cranial nerve is also referred to as CN V or the trigeminal nerve. It is the largest cranial nerve. It is a mixed cranial nerve containing primarily sensory fibers to the skin of the face and scalp, the nasal cavity, and the oral cavity. The motor fibers innervate the muscles of mastication.

FIGURE 209-1. The anatomy of the trigeminal nerve.

The trigeminal nerve originates in the brainstem as a small motor root and a large sensory root. These roots fuse as they leave the brainstem. The trigeminal nerve travels forward into the middle cranial fossa where it expands into the large and crescent-shaped trigeminal ganglion. The trigeminal ganglion divides to give rise to the three divisions of the trigeminal nerve: the ophthalmic nerve (V_1), the maxillary nerve (V_2), and the mandibular nerve (V_3) (**Figure 209-1**). Each of these nerves leaves the middle cranial fossa through its own foramen.

OPHTHALMIC NERVE

The ophthalmic nerve is the smallest branch of the trigeminal nerve. It travels forward in the lateral wall of the cavernous sinus and enters the orbit via the superior orbital fissure. It provides sensory innervation to the forehead, scalp, upper eyelid, cornea, nasal cavity, sinuses, and the orbit. This nerve is not discussed further because it does not innervate any oral or dental structures.

MAXILLARY NERVE

The maxillary nerve is purely sensory. It travels forward in the lateral wall of the cavernous sinus and exits the cranial vault via the foramen rotundum into the pterygopalatine fossa. It then enters the orbit through the inferior orbital fissure to continue on as the infraorbital nerve and emerge on the face. The infraorbital nerve terminates as a sensory nerve to the lower eyelid, upper cheek, nose, and upper lip. The infraorbital nerve gives off the anterior superior alveolar nerves prior to its termination. These nerves supply the maxillary sinus, the maxillary incisors, the maxillary canine teeth, and the maxillary premolar teeth. The anterior superior alveolar nerve occasionally crosses the midline to supply the contralateral maxillary incisors.

The maxillary nerve forms numerous branches in the pterygopalatine fossa. The zygomaticofacial and zygomaticotemporal nerves are cutaneous to the face and temple. The nasal and nasopalatine nerves supply the nasal cavity and floor of the nasal cavity. The nasopalatine nerve exits the nasal canal through the midline incisive foramen just posterior to the central incisors. It provides sensory innervation to the anterior hard palate and associated soft tissues. The greater palatine nerve exits the greater palatine foramen to provide sensory innervation to the posterior two-thirds of the hard palate. The lesser palatine nerve exits the lesser palatine foramen and provides sensory innervation to the soft palate. The greater and lesser palatine nerves exit 1 cm medial to the junction of the second and third molar on the hard palate. The middle superior alveolar nerve provides sensory innervation to the premolars, and occasionally the canine and the first molar teeth. The posterior superior alveolar nerve provides sensory innervation to the molars and occasionally the premolars.

MANDIBULAR NERVE

The mandibular nerve is the largest division of the trigeminal nerve. It is the only division of the trigeminal nerve to contain motor fibers. The mandibular nerve exits the middle cranial fossa via the foramen

ovale. It provides branches to the meninges, the small muscles of the palate, and the medial pterygoid muscle. It divides into a small anterior division and a large posterior division.

The anterior division of the mandibular nerve is primarily motor. It innervates the muscles of mastication (i.e., masseter, temporalis, and lateral pterygoid muscles). The sensory portion of the anterior division is the buccal nerve. This nerve travels between the two heads of the lateral pterygoid muscle, under the masseter muscle, and emerges from the anterior border of the masseter muscle. It travels forward to innervate a small and variable portion of the skin of the cheek. It primarily innervates the mucous membranes of the cheek.

The posterior division of the mandibular nerve is purely sensory. It divides into the auriculotemporal, inferior alveolar, and lingual nerves. The auriculotemporal nerve supplies sensory innervation to the skin of the auricle, external auditory canal, scalp, and temporo-mandibular joint. It conveys postganglionic parasympathetic fibers to the parotid gland.

The lingual nerve descends into the mouth and travels along the lateral surface of the tongue. It supplies sensory innervation to the anterior two-thirds of the tongue and the floor of the mouth. The lingual nerve receives near its origin and conveys the chorda tympani from the facial nerve. The chorda tympani provides taste sensation to the anterior two-thirds of the tongue and preganglionic fibers to the submandibular ganglion for the submandibular and sublingual glands.

The inferior alveolar nerve descends immediately posterior and adjacent to the lingual nerve. It enters the upper one-third of the ramus of the mandible posterior to the lingula to enter the mandibular canal. It provides sensory innervation to the mandible, the mandibular teeth, and the adjacent mucous membranes. The inferior alveolar nerve gives origin to the mental nerve. The mental nerve exits the mental foramen located on the outer surface of the mandible between the first and second premolars. It supplies sensory innervation to the lower lip, the skin of the chin, and the mucous membrane of the chin.

INDICATIONS

Dental nerve blocks can be performed to provide temporary relief of pain. They are often used to provide relief from alveolar ridge fractures, dental caries, dry sockets, mandible fractures, and tooth fractures. Nerve blocks can be performed prior to painful intra-oral procedures such as incision and drainage of dental abscesses and laceration repair to the cheek, lips, oral mucosa, and tongue. Nerve blocks do not distort the local anatomy when compared to

infiltration of the surrounding soft tissue with local anesthetic solution and allow better approximation of the wound edges during suturing. Nerve blocks are an excellent alternative if narcotic analgesics are contraindicated or to be avoided. Local anesthetic solutions containing epinephrine can be utilized to provide longer pain relief and vasoconstriction along the nerve distribution (**Table 209-1**).

CONTRAINDICATIONS

The two absolute contraindications to dental anesthesia include a known hypersensitivity to the anesthetic agent and gross distortion of the anatomic landmarks required to perform the nerve block. Other relative contraindications include an uncooperative patient such as an anxious adult, scared child, or any patient with altered mental status. These patients place themselves and the Emergency Physician at significant risk for injury. It may be most prudent to abort the procedure and perform procedural sedation and analgesia (or general anesthesia in the Operating Room) to ensure the safety of the patient and the Emergency Physician.

The needle used to inject local anesthetic solution should not traverse infected tissue. Injection of the local anesthetic solution into or through infected tissue is also a relative contraindication. These processes may result in spread of the infection into other adjacent tissues or tissue planes. It is possible to cause bacteremia when injecting into infected tissues. Local anesthetic solutions are less effective when injected into areas of infection or inflammation. An infection that tracks along a nerve and into a bone of the face and/or skull is extremely difficult to treat. Evaluate the risks and benefits of injecting through infected tissue and attempt an alternative method of anesthesia if possible.

EQUIPMENT

- Nonsterile gloves
- Antiseptic mouth rinse; any of the following:
 - Hydrogen peroxide
 - Ethanol (7%) with chlorhexidine (0.5%)
 - Povidone iodine solution
 - 0.12% chlorhexidine or Peridex solution
- 4×4 gauze squares
- Cotton-tipped applicators
- Aspirating dental syringe (**Figure 209-2**)
- Local anesthetic solution (**Table 209-1**)

TABLE 209-1 Local Anesthetic Solutions Commonly Used in Dental Anesthesia Procedures

Anesthetic solution	Proprietary name	Time of onset (minutes)	Pulpal duration of action (minutes)	Soft tissue duration of action (minutes)	Maximum dose (mg)*	Maximum adult or pediatric weight-based dose (mg/kg)
1% procaine	Novocaine	6–10	10	15–90	500	7.0
1% procaine with epinephrine		6–10	15	15–120	600	9.0
2% lidocaine	Xylocaine	2–5	10	30–45	300	4.5
2% lidocaine with epinephrine		2–5	60	180–300	500	7.0
3% mepivacaine	Carbocaine	5	5–10	90–120	400	6.6
2% mepivacaine with epinephrine		5	45–60	120–140	400	6.6
4% prilocaine	Citanest	3–5	10–60	60–240	400	6
4% prilocaine with epinephrine		3–5	60–90	180–480	400	6
4% articaine with epinephrine	Septocaine	1–3	45–75	180–300	500	7
0.5% bupivacaine	Marcaine	5	60–90	240–280	90	1.3
0.5% bupivacaine with epinephrine		5	90–120	240–720	90	1.3

*Do not exceed this quantity if the maximum weight-based dose is larger than this number.

FIGURE 209-2. The aspirating dental syringe and local anesthetic cartridges.

- Syringes, 1 mL and 3 mL
- Suction source and tubing
- Yankauer suction catheter
- Topical anesthetic (e.g., viscous lidocaine, viscous benzocaine, or aerosolized benzocaine)
- Overhead light source or headlamp
- 25 and 27 gauge needles, 2 inches long²

The above-listed supplies are required to provide dental anesthesia. They are contained in every Emergency Department. An aspirating dental syringe and anesthetic cartridges, if available, are ideal to perform the nerve blocks (**Figure 209-2**).² Standard 1 to 3 mL syringes armed with a 25 or 27 gauge, 2 inch long needle will work as a substitute. The aspirating dental syringe allows better control of the syringe and the ability to simultaneously aspirate and insert the needle with one hand. This allows the nondominant hand to be used to identify landmarks, retract the cheek or tongue, adjust the light source, and/or use the suction catheter. Many local anesthetic solutions are available in 1.8 mL carpules that fit into the dental aspirating syringe. The carpules are available with the local anesthetic solution and also with or without a vasoconstrictor (usually epinephrine). A dental or multipositional procedure chair would be preferred to the use of a standard cart or gurney.^{4,5} Unfortunately, this may not be available in many Emergency Departments.

Numerous injectable agents are available to provide anesthesia (**Table 209-1**). The most commonly used agents are lidocaine and lidocaine with epinephrine (1:100,000). Longer acting agents are commonly available in the Emergency Department (e.g., bupivacaine and mepivacaine, with and without epinephrine) when a prolonged period of anesthesia is required. Avoid using long-acting local anesthetic agents if the tongue (i.e., inferior alveolar or lingual

nerve blocks) or mucosa (i.e., buccal nerve block) is anesthetized, especially in children, to prevent the patient from biting the area and causing injury.

Relatively new devices are the Accupal (Accupal, Little Rock, AR) and the DentalVibe (Bing Innovations LLC, Boca Raton, FL). These devices are injection preparation tools that prepare the gums before the anesthetic needle is inserted. These devices vibrate and produce ultrasonic tissue stimulation to reduce pain sensation at the needle injection site. The devices are usually not available in the Emergency Department.

Numerous jet injectors for the delivery of local anesthetic agents are commercially available. These devices inject the local anesthetic solution under pressure and in a fine stream into the soft tissues without the use of a needle. The small volume of injected solution and its superficial penetration into the soft tissues only anesthetizes the soft tissues and not the teeth. **Thus, jet injectors cannot be used to anesthetize teeth.** They can be used to provide topical anesthesia.

Several studies have used ultrasound to visualize the nerves involved with dental blocks.^{6,7} There was no more success using ultrasound than the traditional landmark technique.⁷ With more studies and practice, ultrasound may become more widespread in its use for dental anesthesia.

PATIENT PREPARATION

Perform a thorough history and a directed physical examination, dependent on the clinical situation, in any patient undergoing dental anesthesia. Give special attention to the past medical history, past surgical history, current medications, and any history of allergic or adverse reactions to an anesthetic agent. A patient with severe systemic disease may be better served by rescheduling the procedure after appropriate consultation or referral. This will clarify functional reserve and treatment limitations.^{4,5} Any patient with cardiac valvular disease, congenital heart anomalies, artificial heart valves, or other indications should receive antibiotic prophylaxis to help prevent bacterial endocarditis caused from transient bacteremia. Please refer to Chapter 210 for more complete details of antibiotic prophylaxis.

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent for the specific technique to be performed. A formal consent may exist depending upon the institution in which one practices. Some physicians desire a formal signed and dated consent form. Other physicians choose to chart: "All the risks, benefits, and complications were described and discussed with the patient. They understood the procedure described and gave verbal consent for the procedure." This is physician and institution dependent. Place the patient in a well-lighted environment. Reassurance often alleviates a patient's anxiety regarding injections or manipulations and puts them at ease.⁴

Prepare the mucosa at the injection site. Completely dry the mucosa with gauze squares. Apply an antiseptic solution (e.g., 7% ethyl alcohol [ETOH] with 0.5% chlorhexidine solution, diluted povidone iodine, 0.12% chlorhexidine solution, or hydrogen peroxide) to the working area with a cotton ball or gauze square for 15 seconds. Alternatively, the patient can swish 0.12% chlorhexidine mouth rinse or hydrogen peroxide for 30 seconds and then spit it out.

Apply a topical anesthetic agent (e.g., viscous lidocaine or benzocaine with a cotton-tipped applicator or 20% benzocaine spray) for added patient comfort. **It is not recommended to use TAC (tetracaine, adrenalin, and cocaine) or other topical anesthetic combinations that are used for cutaneous laceration repair on mucosal surfaces.** Their use may lead to significant absorption and systemic toxicity.

TECHNIQUES

The general procedure of a dental nerve block will be described. The specific details are contained within each nerve block described below. Identify the anatomic landmarks required to perform the nerve block. Clean the mucous membrane at the injection site with a gauze square. Apply an antiseptic solution. Apply a topical anesthetic and allow it to work for 2 to 3 minutes. Reidentify the anatomic landmarks. Insert a 25 or 27 gauge needle into the appropriate area to deliver the local anesthetic agent. **If the patient experiences paresthesias, do not inject the local anesthetic solution. Paresthesias signify that the tip of the needle is within the nerve bundle.** Withdraw the needle 1 to 2 mm and allow the paresthesias to resolve. This usually takes 5 to 20 seconds. Inject the local anesthetic solution. Allow up to 10 minutes for the local anesthetic solution to take effect. Some Dentists prefer to apply pressure to the area immediately next to the site of the anesthetic injection with a cotton-tipped applicator. This aids in distracting the patient from the pain of injection. Other Dentists “jiggle” the mucous membrane to and fro rapidly as they simultaneously introduce the needle.^{4,5}

SUPRAPERIOSTEAL INFILTRATION (FIELD BLOCK)

This technique is commonly used in dentistry. Excellent anesthesia can be achieved with this technique when it is used to anesthetize a branch of the anterior or middle superior alveolar nerve.^{5,8} This technique deposits local anesthetic agent against the periosteum of the alveolar ridge adjacent to a tooth (**Figure 209-3A**). The local anesthetic agent then infiltrates through the periosteum, the cortical plate of the maxilla, and the medullary bone to anesthetize the nerve root as it leaves the apex of the tooth. This technique works best for teeth with associated thin cortical bone. This includes the maxillary incisor, canine, and premolar teeth. The molars of the maxilla in an adult are less likely to be anesthetized with this technique as the cortical bone in which they lie is relatively thick and a poor conduit for the anesthetic. Supraperiosteal infiltration is also a poor technique for anesthesia of mandibular teeth in the adult patient for the same reasons. In children, the cortical bone of the maxillary molars and the mandible is thin and may allow this technique to be effectively utilized to anesthetize a tooth.

Anatomy: The anterior superior alveolar nerve provides sensory innervation to the ipsilateral medial and lateral incisors, canine, and sometimes the first premolar teeth. The middle superior alveolar nerve provides sensory innervation to the ipsilateral premolars, canine, and first molar teeth.

Patient positioning: Place the patient recumbent in a dental chair with their neck extended 45°. Alternatively, position the patient sitting upright with their back and head firmly set against an examination chair or table.

Landmarks: Use the nondominant hand to grasp and pull the upper lip outward and upward (**Figures 209-3B and 209-3C**). Identify the mucobuccal fold above the tooth to be anesthetized.⁵

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the mucobuccal fold above the tooth to be anesthetized. Firmly grasp the upper lip. Pull it outward and upward to tighten the tissues and allow a clear identification of the maxillary mucobuccal fold (**Figures 209-3B and 209-3C**). Insert a 27 gauge needle through the mucobuccal fold over the center of the tooth to be anesthetized (**Figures 209-3B and 209-3C**). Aim the tip of the needle toward the maxilla. Advance the needle 1.0 to 1.5 cm until it contacts the maxilla (**Figure 209-3A**). Withdraw the needle 1 mm. Aspirate to confirm that the tip of the needle

A

B

C

FIGURE 209-3. Supraperiosteal infiltration of local anesthetic solution. **A.** Illustration of the correct needle position. **B.** Elevate the upper lip and insert the needle through the mucobuccal fold. **C.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw Hill; 2007.)

is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution.

Remarks: The anesthetic will be deposited in a nonoptimal location if the needle is too deep or too shallow. It may take as long as 10 minutes to achieve anesthesia as the local anesthetic solution diffuses through the cortical bone and to the nerve root. **Be careful when using this technique for anesthesia of the incisor or canine teeth because advancing the needle too far may breach the nasal cavity or maxillary sinuses.**

FIGURE 209-4. The supraorbital foramen, infraorbital foramen, and the mental foramen all lie along a straight line drawn through the pupil in the midposition.

INFRAORBITAL NERVE BLOCK

Anatomy: The infraorbital nerve is the terminal branch of the maxillary nerve. It exits the maxilla via the infraorbital foramina and supplies sensation to the ipsilateral upper lip, cheek, lateral nose, and lower eyelid. It may be blocked by either an extraoral or intraoral approach.

Patient positioning: Place the patient recumbent in a dental chair with their neck extended 30°. Alternatively, position the patient sitting upright with their head and back against an examination chair or table with the neck extended 30°. Instruct the patient to slightly open their mouth.

Landmarks: Identify the infraorbital foramen by palpation. It is located below the infraorbital ridge in the mid-pupillary line (Figure 209-4). The mid-pupillary line is a line drawn in the sagittal plane (i.e., vertical) through the pupil while the patient is staring straight ahead.

Needle insertion and direction (extraoral approach): Identify the infraorbital foramen as above. Clean and prep the skin over the infraorbital foramen. Instruct the patient to close their eyes. Insert a 25 or 27 gauge needle through the skin overlying the infraorbital foramen (Figure 209-5). Advance the needle to just beneath the subcutaneous tissue. **Do not enter the infraorbital canal as this may damage the nerve.** Aspirate to confirm that the tip of the

FIGURE 209-5. The extraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle.

FIGURE 209-6. The intraoral approach to the infraorbital nerve block. **A.** Location of the nerve. **B.** Insertion of the needle. **C.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

needle is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution. Massage the area over the infraorbital foramen for a few seconds to ensure optimal infiltration.

Needle insertion and direction (intraoral approach): Clean, prep, and apply a topical anesthetic agent to the mucosa opposite the first maxillary premolar. Place the nondominant index finger over the infraorbital foramen (Figure 209-6). Retract the upper lip using the nondominant thumb. Identify the mucobuccal fold above the first premolar. Insert a 25 or 27 gauge needle through the mucobuccal fold. Advance the needle toward the nondominant index finger situated over the infraorbital foramen (Figures 209-6B and 209-6C). Stop advancing the needle when the tip is felt beneath the index finger. The estimated depth of penetration of the needle tip is 1.0 to 1.5 cm in an older child or an adult and 0.5 to 1.0 cm in a younger child. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1 to 2 mL of local anesthetic solution.

Remarks: Be careful not to penetrate too deeply when performing the intraoral approach. The infraorbital venous plexus may be disrupted and result in a hematoma. The globe may also be accidentally penetrated. Avoid these complications by positioning the nondominant index finger over the infraorbital foramen and using it to palpate and track the advancing needle tip. The intraoral approach is the preferred technique.

NASOPALATINE NERVE BLOCK

Anatomy: The nasopalatine nerve provides sensory innervation to the anterior one-third of the hard palate (Figure 209-7A). It exits the maxilla via the incisive foramen in the midline and 0.5 cm posterior to the central incisors.

Patient positioning: Place the patient recumbent in a dental chair with their head extended 45°. Alternatively, place the patient supine with a rolled sheet beneath their shoulder blades to assist in neck extension. Instruct the patient to fully open their mouth.

Landmarks: The incisive foramen lies in the midline and approximately 5 mm posterior to the central incisors of the maxilla. Overlying the incisive foramen is the incisive papilla, a soft tissue elevation.

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the mucosa on the anterior one-third of the hard palate. Identify the incisive foramen by first identifying the incisive papilla. Insert a 27 to 30 gauge needle, with the bevel facing the hard palate, from a position immediately lateral to the edge of the incisive papilla (Figures 209-7B and 209-7C). Advance the needle 3 to 4 mm toward the midline or until bone is identified. Aspirate to

FIGURE 209-7. Anesthesia of the palate. **A.** Sensory innervation of the palate. **B.** Nasopalatine nerve block. **C.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.) **D.** Greater palatine nerve block. **E.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

confirm that the tip of the needle is not within a blood vessel. Inject 0.25 to 0.35 mL of local anesthetic solution. The area surrounding the injection site will blanch upon deposition of the local anesthetic solution.^{4,5}

Remarks: This is a particularly painful injection due to the adherent nature of the mucosa to the underlying hard palate. Topical anesthetics will provide adequate preinjection anesthesia. Some clinicians use a cotton-tipped applicator or a blunt instrument to put pressure on the incisive papilla for 30 seconds prior to and during the injection.⁵ This seems to defer the attention of the patient and make the injection more bearable. **Be careful not to penetrate too deeply with the needle and enter the incisive foramen.** Insertion into the incisive foramen will cause severe pain. **Injection into the incisive foramen can result in permanent nerve damage.**^{4,5} The mucosa of the hard palate receives its blood supply from the hard palate. Injection of more than 0.4 mL will elevate the mucosa from the hard palate and result in mucosal necrosis. This block may be performed to repair lacerations of the mucosa of the anterior hard palate.

GREATER PALATINE NERVE BLOCK

Anatomy: The greater palatine nerve provides sensory innervation to the ipsilateral posterior two-thirds of the hard palate (Figure 209-7A). It enters the oral cavity via the greater palatine foramen. The greater palatine foramen lies between the second and third maxillary molar and approximately 1 cm onto the hard palate.

Patient positioning: Place the patient recumbent in a dental chair with their head extended 45°. Alternatively, place the patient supine with a rolled sheet beneath their shoulder blades to assist in neck extension. Instruct the patient to fully open their mouth.

Landmarks: The greater palatine foramen lies 1 cm medial to the gingival junction of the second and third maxillary molar (Figure 209-7D).

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the hard palate adjacent to the second and third maxillary molars. Insert a 27 to 30 gauge needle 1 cm medial to the junction of the second and third maxillary molars (Figures 209-7D and 209-7E). Ensure that the tip of the needle is held at 90° to the curve of the palate. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 0.25 to 0.35 mL of local anesthetic solution. The area surrounding the injection site will blanch upon deposition of the local anesthetic solution.^{4,5}

Remarks: This block may be performed to repair lacerations of the mucosa of the hard palate. The mucosa of the hard palate receives its blood supply from the hard palate. Injection of more than 0.4 mL will elevate the mucosa from the hard palate and result in mucosal necrosis. The position of the lesser palatine foramen is 2 to 4 mm posterior to the greater palatine foramen. The lesser palatine nerve provides sensory innervation to the soft palate and uvula. If anesthetized, as it often is when blocking the greater palatine nerve, the patient may experience a feeling of dysphagia or throat closure. Reassurance is usually adequate to alleviate the patient's anxiety until the anesthesia wears off.

POSTERIOR SUPERIOR ALVEOLAR NERVE BLOCK

Anatomy: The maxillary nerve exits the skull via the foramen rotundum. It then courses anteriorly into the pterygopalatine fossa and divides into its constituent branches. The posterior superior alveolar nerve provides sensory innervation to the maxillary molar teeth and their associated mucosal tissues.

Patient positioning: Place the patient semi-recumbent in a dental chair with their head extended 30°. Alternatively, place the patient

sitting upright with their head and back firmly against the examination chair or table and their head extended 30° to 45°. Instruct the patient to fully open their mouth.

Landmarks: Pull the buccal mucosa laterally and identify the inferior-most posterior portion of the zygoma (Figure 209-8A). It lies posterior, lateral, and superior to the third maxillary molar. The pterygomaxillary fissure lies posterior, medial, and superior to the vestibule between the third maxillary molar and the posterior zygoma. The pterygopalatine fossa can be reached by following the pterygomaxillary fissure superiorly and medially.^{4,5}

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the recess posterior and lateral to the maxilla. Insert the nondominant index finger between the maxillary molars and the cheek (Figure 209-8A). Palpate the zygomatic process of the maxilla with the index finger. Rotate the index finger 180° so that the pad is against the patient's cheek (Figure 209-8B). Apply outward pressure to move the cheek away from the teeth. Place the needle along the middle of the nail plate of the index finger. Aim the needle and syringe along the index finger (Figure 209-8B). The needle and syringe should be aimed posteriorly, superiorly, and medially (Figures 209-8C and 209-8D). Insert and advance the needle 2.5 cm along the index finger. If the needle contacts bone, withdraw the needle completely and direct it more laterally.^{4,5} Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 3 mL of local anesthetic solution.

Remarks: Bend the needle 30° at the hub to assist in achieving a medial direction of the needle. **Do not bend the needle more than 30° as the needle may fracture. It is extremely important to never change the direction of a needle once it is inserted.** This is associated with an increased risk of needle breakage requiring an operative procedure to recover the needle segment. **Never force the needle.** The needle is inappropriately positioned if it is meeting resistance. Abort the procedure, reidentify the landmarks, and reattempt the procedure.^{4,5} Occasionally, the first molar is only partially anesthetized by this block. Consider supplementation of this block with a supraperiosteal infiltration of the first molar.

MENTAL NERVE BLOCK, INTRAORAL APPROACH

Anatomy: The mental nerve is one of the two terminal divisions of the inferior alveolar nerve. It provides sensory innervation to the ipsilateral skin and mucosa of the lower lip and chin. It exits the bony mandible at the mental foramen.

Patient positioning: Place the patient recumbent in a dental chair. Alternatively, place the patient sitting upright or supine with their head against the examination table and in the neutral position. Instruct the patient to slightly open their mouth.

Landmarks: The mental foramen lies in the same plane as the infraorbital foramen and the mid-pupillary line (Figure 209-4). The mental foramen is located approximately 1 cm beneath the gum line between the first and second premolar.

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the oral mucosa overlying the mental foramen. Grasp the lower lip with the nondominant hand. Pull it outward and downward (Figures 209-9A and 209-9B). Insert a 27 gauge needle into the mucobuccal fold between the first and second premolar (Figures 209-9A and 209-9B). Advance the needle medially until it contacts the mandible. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1.5 to 2.0 mL of local anesthetic solution.

Remarks: The mental nerve block, as the infraorbital nerve block, has an intraoral and an extraoral approach. The extraoral approach will not be discussed as it is more painful and there is no benefit to

FIGURE 209-8. The posterior superior alveolar nerve block. **A.** The nondominant index finger is inserted and positioned. **B.** The cheek is retracted. **C.** The proper direction for insertion and advancement of the needle. **D.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

its use over the intraoral approach. A description of the extraoral approach to the mental nerve block is found in Chapter 156. A near midline lower lip or chin injury may necessitate bilateral mental nerve blockade due to the midline crossover from each of the mental nerves.⁴

BUCCAL NERVE BLOCK

Anatomy: The buccal nerve is one of the main branches of the mandibular nerve. It travels down the medial aspect of the ramus of the mandible anterior to the inferior alveolar neurovascular bundle. It crosses from the medial mandible into the soft tissue of the cheek at the level of the occlusal plane. It supplies the sensory innervation to the mucous membrane of the cheek and vestibule.¹ It innervates, to a variable degree, a small patch of skin over the cheek.

Patient positioning: Place the patient recumbent in a dental chair with their head extended 30°. Alternatively, place the patient sitting with their head and back firmly against an examination chair or upright table with their head extended 30° to 45°. Instruct the patient to fully open their mouth.

Landmarks: Visually identify the third mandibular molar. Palpate the anterior border of the ramus of the mandible. The buccal nerve traverses the anterior border of the ramus of the mandible, posterior and slightly lateral to the third molar at the level of the occlusal plane.

Needle insertion and direction: Clean, prep, and apply a topical anesthetic agent to the oral mucosa over the anterolateral border of the ramus of the mandible. Place the thumb of the nondominant hand on the inner surface of the cheek. Pull the cheek outward (Figures 209-10A and 209-10B). Insert a 27 gauge needle 1 mm lateral to the anterior border of the ramus of the mandible and at

A

B

FIGURE 209-9. The intraoral approach to the mental nerve block. **A.** Artist illustration. **B.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

the level of the occlusal plane (**Figures 209-10A and 209-10B**). Advance the needle 3 to 4 mm into the soft tissues. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

Remarks: Buccal nerve blocks are used when extensive intraoral manipulation is anticipated, when buccal manipulation or repair is required, or for the incision and drainage of an abscess. It provides additional patient comfort. The block is nearly always performed as an adjunct to an inferior alveolar, maxillary, or posterior superior alveolar nerve block.⁵

INFERIOR ALVEOLAR NERVE BLOCK

Anatomy: The lingual and inferior alveolar nerves are two of four branches of the mandibular nerve. The nerves initially travel together and inferiorly on the medial side of the mandibular ramus (**Figure 209-11A**). The lingula is a palpable bony landmark immediately anterior to the mandibular foramen. The inferior alveolar nerve courses posterior to the lingula and enters the mandibular

A

B

FIGURE 209-10. The buccal nerve block. **A.** Artist illustration. **B.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

canal via the mandibular foramen. It continues to travel anteriorly within the mandible to provide sensory innervation to the body of the mandible, the mandibular teeth, and the overlying oral mucosa. One of the terminal branches of the inferior alveolar nerve is the mental nerve. The inferior alveolar nerve may be blocked by the classic open-mouth approach or the closed-mouth approach.

Patient positioning: Place the patient in a dental chair with their head neutral such that the occlusal surface is parallel to the floor. Alternatively, place the patient sitting upright in an examination chair or on a gurney with their head positioned firmly against the back of the gurney or chair. Instruct the patient to fully open their mouth. Perform the open-mouth approach if the patient can fully open their mouth. Perform the closed-mouth approach if the patient has trismus or cannot fully open their mouth.

Landmarks: Identify by palpation the anterior border of the ramus of the mandible within the mouth, the coronoid notch within the mouth, and the posterior border of the ramus of the mandible externally (**Figure 209-11B**). Approximately equidistant from these two points lie the lingual and the inferior alveolar nerves. Palpate

FIGURE 209-11. The inferior alveolar nerve block. **A.** The course of the inferior alveolar nerve and the lingual nerve along the ramus of the mandible. **B.** The anatomy of the external surface of the mandible. **C.** Positioning for the open-mouth approach. **D.** Proper needle insertion and direction for the open-mouth approach. **E.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. the lingula of the ramus of the mandible. It is a bony projection on the medial surface of the ramus of the mandible and 1 cm above the occlusive plane.

Needle insertion and direction (open-mouth approach): Clean, prep, and apply a topical anesthetic agent to the inner surface of the ramus of the mandible. Stand opposite the side to be blocked. Place the thumb of the nondominant hand on the anterior border of the ramus of the mandible. Move the thumb posteromedially to identify the lingula. Place the index finger of the nondominant hand against the extraoral border of the mandibular ramus just above the angle of the mandible. Grasp the ramus between the thumb and the forefinger (**Figure 209-11C**). Pull the cheek outward using the nondominant thumb as a lever. Place a 27 gauge, 2 inch needle on a 3 mL syringe that contains local anesthetic solution. A 5 mL syringe is too large for this approach. A syringe smaller than 3 mL will not carry enough anesthetic.

Introduce the needle from the opposite side (**Figures 209-11D and 209-11E**). Align the tip of the needle toward the lingula with the barrel of the syringe between the contralateral first and second premolars (**Figures 209-11D and 209-11E**). Hold the syringe parallel to the occlusal plane and 3 to 4 mm above the premolars. Insert the needle into the oral mucosa just superior and posterior to the lingula. Advance the needle until the tip contacts the ramus of the mandible. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

The above technique is optimal if the operator is right-handed and a right-sided inferior alveolar block is attempted. If the operator is right-handed and attempting a left-sided inferior alveolar nerve block, it is still necessary to stand opposite the side to be anesthetized with the syringe in the dominant hand. Place the nondominant arm over and around the patient's head so that the thumb of the nondominant hand can contact the anterior border of the mandibular ramus and the index finger can grasp the posterior border above the angle of the mandible. The remainder of the technique is the same.

Needle insertion and direction (closed-mouth approach): This method can be used when the patient cannot fully open their mouth due to an abscess, edema, mandible fractures, trismus, or if the mandible is wired closed to the maxilla. This approach deposits the local anesthetic solution superior to the site of the classic open-mouth approach. The local anesthetic solution will descend due to gravity to bathe the inferior alveolar nerve and provide adequate anesthesia.

Place the nondominant thumb on the inner surface of the cheek. Pull the cheek outward. Place a 27 gauge needle on a 3 mL syringe that contains local anesthetic solution. Place the needle and syringe parallel to the occlusal plane and aligned along the junction of the maxillary molars and their gingiva (**Figure 209-11F**). Direct the needle just medial to the ramus of the mandible (**Figures 209-11F and 209-11G**). Advance the needle 3 cm through the mucosa. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 2 mL of local anesthetic solution.

Remarks: It is crucial that the tip of the needle contacts the mandible in the open-mouth approach. The needle is usually advanced in the tissue 0.5 to 1 cm before the mandible is encountered. The needle is most likely inappropriately placed and deposition of anesthesia will not produce the desired results if the mandible is not encountered. Remove the needle, reidentify the appropriate anatomic landmarks, and reattempt the procedure if the mandible is not encountered. The buccal, inferior alveolar, and lingual nerves must be blocked on one side to achieve complete anesthesia of the hemimandible. Facial nerve paralysis can occur if the needle is inserted too far posterior and enters the capsule of the parotid gland. This paralysis is usually transient and resolves as the anesthetic wears off.

LINGUAL NERVE BLOCK

Anatomy: The lingual nerve is a branch of the mandibular division of the trigeminal nerve. It travels with the inferior alveolar nerve until the inferior alveolar nerve enters the mandible. The lingual nerve leaves the medial aspect of the mandibular ramus and penetrates the posterior tongue at the level of the occlusive plane just medial to the third mandibular premolar. It courses anteriorly to provide sensory innervation to the anterior two-thirds of the tongue, the floor of the mouth, and the lingual mucous membrane.¹

Patient positioning: Place the patient in a dental chair with their head neutral such that the occlusive surface is parallel to the floor. Alternatively, place the patient sitting upright in an examination chair or on a gurney with their head firmly against the back of the gurney or chair. Instruct the patient to fully open their mouth.

Landmarks: Identify the lingual side of the second mandibular molar. The injection site is 1 cm medial to the second mandibular molar.

Needle insertion and direction: Approach the patient from the contralateral side. Move the tongue upward or toward the contralateral side with a tongue blade. Insert a 27 gauge, 2 inch needle into the mucosa 1 cm medial to the second mandibular premolar (**Figures 209-12A and 209-12B**). Advance the needle posteriorly 1 cm. Aspirate to confirm that the tip of the needle is not within a blood vessel. Inject 1.0 to 1.5 mL of local anesthetic solution.

Remarks: The inferior alveolar nerve and the lingual nerve can be, and usually are, blocked simultaneously during an inferior alveolar nerve block. The lingual nerve, however, can be blocked in an isolated fashion. Perform an isolated lingual nerve block only when the initial combined block has failed or for isolated tongue lacerations.^{1,5} This is an optimal block for tongue laceration repair. However, bilateral lingual nerve blocks may be necessary.

ASSESSMENT

Anesthesia is usually achieved within 5 minutes of the injection. However, depending upon the particular injection and the local anesthetic used, anesthesia can be achieved anywhere from 20 seconds to 10 minutes. The block was properly performed if the patient experiences anesthesia. Repeat the block if anesthesia is not achieved by 10 minutes.

AFTERCARE

The aftercare of dental anesthesia is minimal. Reexamine the area of the local anesthetic injection before the patient is discharged to ensure that a hematoma has not developed. **Instruct the patient to use caution as there is no sensation in the area anesthetized.** Encourage them to refrain from meals, chewing gum, hot beverages, aggravated scratching, placing foreign bodies in the mouth, or anything that may cause injury to the anesthetized area. Parents must be informed to discourage children from testing the anesthetized area by biting or chewing. Many Dentists and Physicians place a cotton roll, or rolled 2×2 gauze, between the area anesthetized and the teeth to provide added protection from a self-inflicted bite injury.^{4,5}

COMPLICATIONS

Any patient receiving dental anesthesia has the potential to develop complications. The key is to have knowledge of these complications and be prepared to deal with them should they occur. Most severe complications will declare themselves in a rapid fashion. These severe complications include intravascular injection of local anesthetic, allergic reactions to the local anesthetic, cardiovascular toxicity, neurologic toxicity, seizures, and unintentional overdose.

FIGURE 209-12. The lingual nerve block. **A.** Artist illustration. **B.** Photo. (Used with permission from Hadzic A: *New York School of Regional Anesthesia Textbook of Regional Anesthesia and Acute Pain Management*. New York: McGraw-Hill; 2007.)

Allergic reactions can occur from the latex vial/carpule seal or the preservative in the local anesthetic.⁹ These complications can be avoided by aspiration before injection, obtaining an appropriate history of prior anesthesia, and cautious calculation of anesthetic dosages, respectively.^{4,5,8}

Late complications of dental anesthesia include hematomas, neuropathy, infection, and trismus.^{4,5} Hematomas after dental anesthesia occur after the inadvertent puncture of an artery or vein. Arterial hematomas enlarge more rapidly and are usually more painful than venous hematomas. They can cause a significant facial deformity. Hematomas following dental anesthesia are usually of little significance, require no intervention, and resolve spontaneously with time. A proper preprocedural history should determine if the patient is using any anticoagulants or blood thinners, has a real or potential bleeding disorder, or had adverse bleeding complications from previous procedures. Treatment initially involves applying cold packs. Heat in the form of an externally placed heating pad should be used to help disintegrate the clot after 24 hours.^{4,5}

A peripheral neuropathy can occur in the form of prolonged anesthesia, paresthesias (i.e., burning or itching sensation), hyperesthesias (i.e., increased sensitivity to noxious stimuli), and dysesthesias (i.e., painful sensation to non-noxious stimuli). This may be a result of direct damage to the nerve from traumatic needle insertion, hemorrhage or hematoma within the nerve sheath, deposition of local anesthetic into a foramen or canal causing pressure injury to the nerve, or chemical injury to the nerve.^{10,11} Reduce the risk of causing a neuropathy by avoiding injections into a foramen, using a small gauge needle, and withdrawing the needle slightly before injection if the patient should feel a shock or paresthesias with needle insertion.^{4,5} While many nerve injuries are temporary and will resolve with time, some can be permanent.¹¹

Infection due to dental anesthesia is rare but does exist. Follow several simple measures to minimize potential infections. Never inject through an infected area. Doing so may carry bacteria through facial planes into deeper compartments. Refrain from multiple injections (i.e., needle misadventures) as this increases the risk of iatrogenic infection. This is easily resolved by appropriately identifying the anatomic landmarks prior to needle insertion.

Needle breakage can occur as a result of manufacturing defects or operator imprudence. **To prevent needle breakage, never exert force against resistance.** Resistance signifies that the tip of the needle is against bone or a tooth. Withdraw the needle and reattempt insertion if this occurs. **Never advance the needle to the hub.** The greatest percentage of needle breaks occur when the needle is inserted to the hub.^{4,5} **Never redirect the needle after it is inserted through the skin or mucosa.** This puts abnormal force on the needle and potentiates breakage. The needle may inadvertently be in an undesired anatomic location. Withdraw the needle completely, identify the appropriate anatomic landmarks, and reinsert the needle. Do not bend the needle as this can weaken it and make it more prone to breakage. If a needle breaks, grasp the fragment with a forceps or hemostat and remove it from the soft tissue. If the needle fragment is not palpable with an instrument, consult a Dentist or Oral Surgeon for possible removal. The consultant may choose to see the patient in the Emergency Department, see the patient in their office within 24 to 48 hours, or leave the needle fragment in place and not remove it.

SUMMARY

Dental anesthetic techniques are easy to learn, simple to perform, and effective in providing temporary pain relief. The required equipment is readily available in every Emergency Department. Consider using local anesthetic agents that contain epinephrine to provide significantly longer analgesia than those without epinephrine. A rapidly performed local anesthetic injection goes a long way toward patient satisfaction.

Dental Abscess Incision and Drainage

Richard Dean Robinson and Peter S. Kim

INTRODUCTION

Patients frequently present to the Emergency Department complaining of a “toothache.” There are multiple common causes of toothache pain and similarly multiple etiologies for a dental abscess (Table 210-1).¹ Distinguishing the type of dental abscess can have an impact on the treatment decisions, prognosis, and patient morbidity.²⁻⁵ Accurate diagnosis and proper treatment of these maladies requires that the Emergency Physician have a basic understanding of dental anatomy, pathophysiology, and simple dental treatment protocols. There are many complications of odontogenic infections (Table 210-2).⁶⁻⁸ Many of these conditions can be managed initially through the Emergency Department. The prudent Emergency Physician must have a clear understanding that these infections can rapidly become complicated requiring timely consultation or referral.

ANATOMY AND PATHOPHYSIOLOGY

Teeth are essentially composed of three layers: the outermost enamel, underlying dentin, and the pulp which is the deepest layer (Figure 210-1). The dentin and pulp are living tissues that are sensitive to noxious stimuli. The crown is covered with enamel while the root is covered with a substance known as cementum. Cementum helps attach the tooth to the surrounding alveolar bone via the periodontal ligament (PDL). The neurovascular supply enters the pulp through the apical foramen at the root apex. The pulp contains only pain transmitting neuronal fibers while the PDL contains both pain-sensitive and pressure-sensitive fibers.⁹ Anatomic structures in the body limit and direct the spread of infection in a predictable way. These structures include fascial layers, ligaments, tendons, muscles, and bone.¹⁰

Dental abscesses arise when bacteria penetrate the normal anatomic and physiologic barriers of the tooth and surrounding structures. This can lead to a localized collection of purulence contained within the tooth (i.e., a pulp abscess) or around the apex of the tooth (i.e., a periapical abscess) (Figure 210-2). Alternatively, a dental abscess may localize to the supporting structures of the tooth (i.e.,

a periodontal abscess) or strictly to the adjacent soft tissues (i.e., a pericoronitis) (Figure 210-2).

PULPAL OR PERIAPICAL ABSCESSES

Dental abscesses often arise from pulp necrosis secondary to dental caries or a defective restoration.^{1,3,4,7-9,11,12} Dental caries are commonly known as dental decay or “cavities.” This process represents direct destruction of the tooth substance by acidic bacterial products of normal oral flora. A carious tooth may not initially be painful. However, as bacterial inflammatory products invade the dental pulp during disease progression, the tooth will consequently become sensitive.^{1-3,9,13,14} This is known as pulpitis which typically presents with nonlocalizable and intermittent symptoms. This process may initially be reversible by routine dental treatment (e.g., a filling) but the pulp will rapidly necrose and die if it becomes infected. If the infectious process is allowed to continue, products from the necrotic pulp may escape the confines of the tooth via the apical foramen and begin to involve the PDL and surrounding alveolar bone. This is known as a periapical abscess and makes the infected tooth easily localizable with intermittent or constant sensitivity, and/

FIGURE 210-1. The anatomy of a tooth.

FIGURE 210-2. Locations of common dental abscesses.

or tenderness to gentle percussion (**Figure 210-3**).^{1-3,5,9,11,14} At this stage of the disease process, a root canal would be indicated which is essentially an incision and drainage procedure performed on the inside of a tooth by an Endodontist.^{9,11}

If left unchecked, however, the bacterial products of a periapical infection and the host's immune response to it can lead to progressive destruction of dental supporting tissues including the alveolar bone. At this point the tooth will become increasingly mobile. The infection will follow the path of least resistance as it penetrates through the alveolar bone into the surrounding soft tissues.^{9,11} It may perforate laterally to form a vestibular abscess (**Figures 210-2 and 210-4A**), or alternatively, it may perforate medially to form a palatal or lingual abscess (**Figures 210-2 and 210-4B**). Further spread will be dictated by the proximity of muscle attachments and fascial planes.^{3,5,9,11,14-16} The appropriate treatment for an abscessed tooth depends on the extent of the infection. It may include endodontic treatment, incision and drainage, extraction, or a combination of these.^{9,11} An incision and drainage procedure is warranted if the infectious process extends outside the alveolar bone and involves proximal soft tissues.^{5,9,11,14,15}

The extension of infectious products beyond the root apex can lead to a multitude of clinical signs and symptoms involving the

FIGURE 210-4. The spread of dental abscess. A pulp abscess progresses to a periapical abscess that perforates the alveolar plate. **A.** Labial or buccal perforation leads to a vestibular abscess. **B.** Palatal or lingual perforation leads to a palatal or lingual abscess, respectively.

head and neck. Swelling, erythema, warmth, fluctuance, and spontaneous drainage of purulence via a sinus tract or fistula may be seen intraorally or extraorally (**Figure 210-3B**). A localized or generalized cellulitis may be present. There is often a foul breath odor.^{1,5,11,15} One or more of the numerous fascial spaces of the head and neck may become involved via direct extension.^{3,5,9,11,13,15-21} Systemic symptoms may occur including fever, malaise, anorexia, and leukocytosis.^{5,6,11,13,15,17} Structures immediately adjacent to the oral cavity may also become involved. This can result in complications such as trismus, reactive sinusitis, lymphadenopathy, osteomyelitis, cavernous sinus thrombosis, airway compromise, and/or a brain abscess.^{3,6,16-21}

Dental infections extending into any of the fascial compartments of the head and neck are dangerous, can rapidly progress, and are considered complicated infections.^{3,5,6,9,11,15,17-21} The classic example is Ludwig's angina, a potentially life-threatening cellulitis involving the sublingual, submental, and submandibular spaces bilaterally. **This represents an immediate threat to the airway.** Patients typically will appear toxic with systemic signs and symptoms. Classically, patients will present with an elevation of the mouth, submandibular swelling, dysphagia, and voice changes.^{6,10,16,18,20,21} Infectious extensions into the lateral pharyngeal, retropharyngeal, and prevertebral spaces are rare and can lead to disastrous complications such as aspiration, mediastinitis, and airway compromise. A retropharyngeal space measuring greater than 3 to 5 mm on lateral soft tissue neck radiographs or computed tomography (CT) scans is indicative of airway compromise.¹⁵ **Consider rapid and aggressive management with prompt surgical consultation, broad-spectrum antibiotics, and early airway intervention in patients who are suspected of manifesting any of these processes.**^{3,13,15-20}

PERIODONTAL ABSCESSES

Poor dental hygiene and poor nutrition lead to local inflammation of the tissues surrounding and attaching the tooth to its socket allowing bacterial penetration.^{7,8,12} Early periodontal disease is isolated to the gingiva and is known as gingivitis.^{5,22} Alveolar bone may be destroyed as the disease progresses leading to gingival pockets and tooth mobility.^{1,5,23} Food debris or plaque may become trapped within these pockets and create a localized infection known as a

FIGURE 210-5. A cracked tooth (green arrowheads) led to the lateral periodontal abscess (blue arrowheads). (Used from www.commonswiki.org/wiki/Category:Periodontal_abscess#/media/File:Cracked_tooth_lateral_periodontal_abscess.jpg).

periodontal abscess (**Figure 210-5**).^{4,5,22} Periodontal disease is very common in pregnant women.

Patients may complain of bleeding, foul oral odor, bad taste, loose teeth, pain, or swelling. The physical examination will reveal gingival tissue that may be erythematous or necrotic and bleed easily. Heavy accretions of dental plaque and calculi may be present. An abscess may present as a focal swelling, tooth mobility, pain on percussion, and/or purulence that is expressible from the gingival sulcus.^{1,5,22,23} It may be impossible with current dental caries to differentiate a periapical abscess from a periodontal abscess without radiographs.^{3,5} In fact, both lesions may occur simultaneously.²³ Periodontal disease may be sufficiently advanced such that teeth may be so mobile they cannot be salvaged and require extraction for definitive therapy.⁵

True periodontal abscesses rarely spread beyond the local dentoalveolar structure. If present, urgent referral may be required.^{3,4} Treat an isolated periodontal abscess with dental anesthesia, incision and drainage, and dilute peroxide (e.g., a 1:5 solution or 5%) or chlorhexidine rinses. Prescribe oral antibiotics for advanced disease evidenced by spread to adjacent tissues, if there is anticipated delay to definitive care, and/or for systemic manifestations.^{1,3-5,23} Appropriate antibiotic options include penicillin, clindamycin, or erythromycin. Refer patients with these lesions to a Dentist within 24 to 48 hours for definitive care and to avoid recurrence of disease.^{1,3,5}

PERICORONITIS

Inflammation can occur around the crown of any erupting tooth and is common around impacted teeth, especially the third molars.^{1,3,4,7,8,12,24} This condition is known as pericoronitis (**Figure 210-6**). It is often exacerbated by impaction of food under soft tissues. Progression of the primary process or overzealous treatment can easily lead to extension of the infection posteriorly to multiple contiguous spaces, including the retropharyngeal space.^{1,3,24,25} Simple cases are easily managed in the Emergency Department. Always maintain a very low threshold for consultation and referral of these patients with complicated presentations.

FIGURE 210-6. Soft tissue (green arrowhead) over the partially erupted left lower third molar with inflammation and pus is known as a pericoronitis. (Used from www.commons.wikimedia.org/wiki/Category:Pericoronitis#/media/File:38_pericoronitis_with_pus.jpg).

Treatment of pericoronitis may include dental anesthesia, direct saline irrigation, warm salt water rinses, dilute peroxide or chlorhexidine rinses, and oral analgesics. The presence of swelling, trismus, and inflammation may be severe enough to warrant a course of oral antibiotics.¹ Some authors advocate antibiotic coverage in essentially all cases.^{1,15,24} Definitive treatment requires the completed eruption or extraction of the tooth. Refer the patient to a Dentist or Oral Surgeon for definitive care within 24 to 48 hours.

RADIOLOGIC EVALUATION

Odontogenic infections often require a radiologic evaluation. This may include mandibular plain films, a Panorex film, an ultrasound, and a CT scan. This is because the clinical examination does not always lead to a definitive diagnosis. Panorex x-rays, if available, are traditionally used to evaluate the teeth. This is time-consuming because the order must be written, the order must be put in the order system, the patient needs to be transported to the Radiology Department for the study, the patient needs transportation back to the Emergency Department, and the Radiologist needs to read the film. Mandibular films or a CT scan will work if a Panorex unit is not available, with the same time-consuming process. In addition, there is the issue of ionizing radiation. Bedside ultrasonography has been used to determine if an abscess is present and to perform an incision and drainage.²⁶ This is an accurate, inexpensive, and quick technique that does not use ionizing radiation.

INDICATIONS

Incision and drainage of a periapical or periodontal abscess is indicated when there is clinical evidence of alveolar penetration and soft tissue spread.^{14,15} Incision and drainage achieves several key objectives including symptomatic relief via decompression, creation of a portal for irrigation, means of obtaining a sample for culture, and exposure of anaerobic bacteria to air thus inhibiting growth.¹⁰ Some authors recommend incision and drainage for purely cellulitic processes.^{4,5,16} Standard recommendation is to undergo incision and drainage sooner rather than later as progression of abscess

development increases the incidence of complications and morbidity.²⁷

Extraoral incision and drainage is indicated only for dental infections progressing toward inevitable spontaneous extraoral drainage.^{3,15} Drain all other dental abscesses intraorally.

CONTRAINDICATIONS

A review of the current literature reveals no direct contraindications to the incision and drainage of a dental abscess. Maintain a low threshold for consultation and referral to a surgical specialist for any patient with rapidly progressing infections, dyspnea, dysphagia, fascial space involvement, a temperature greater than 101°F (38.3°C), white blood cells >10,000, severe trismus manifested by mandibular opening less than 10 mm or the inability to adequately visualize the hypopharynx, a toxic appearance, compromised host defenses, or children.^{3,11,15,28}

EQUIPMENT

- #15 scalpel blade on a handle
- #11 scalpel blade on a handle
- Povidone iodine or chlorhexidine solution
- Minnesota retractor
- Weider tongue retractor
- Frazier suction catheter
- Suction source and tubing
- Needle driver
- Hemostat
- Suture, 4–0 and 5–0 silk
- Gelfoam
- Penrose drain, 0.25 inch wide
- Light source, overhead or headlamp

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain dental radiographs if the infection is from a dental source.^{5,11,15} Obtain an informed consent for the procedure. Provide adequate anesthesia, ideally in the form of a dental block. Obtain a separate informed consent for the dental block. **Direct infiltration into the area of purulence does not achieve adequate anesthesia and risks spreading the infection by inoculation.^{3,5}** Dental blocks may require augmentation with direct infiltration anterior and posterior to the abscess. Anesthetize the areas adjacent to the abscess last to avoid seeding. Refer to Chapter 209 for a complete discussion of dental analgesia and anesthesia. The application of procedural sedation (Chapter 159) may be required if adequate local anesthesia is not possible.¹⁵

Prophylaxis to prevent infective bacterial endocarditis should be addressed in appropriate patients prior to incision and drainage of a dental abscess in accordance with the policy put forth by the American Dental Association. Further information and specific antibiotic regimens can readily be found on the websites of the American Heart Association and American Dental Association (Table 210-3).^{29,30}

TECHNIQUES

SIMPLE INTRAORAL INCISION AND DRAINAGE

There are two techniques for the intraoral incision and drainage. The first technique is to make a simple stab incision with a #11 scalpel blade in the area of greatest fluctuance and in the

TABLE 210-3 Prophylactic Regimens for Endocarditis in Patients Undergoing Dental or Oral Surgical Procedures

Situation	Antibiotic choice***	Adult dose	Pediatric dose**

	Or		
	Ceftriaxone*		

IM, intramuscular; IV, intravenous; PO, oral.

*Administer the antibiotics 30 to 60 minutes prior to the procedure.

**The pediatric weight-based dose should not exceed the adult dose.

***Do not use cephalosporins in a patient with a history of a penicillin allergy and any of the following: anaphylaxis, angioedema, respiratory difficulties, urticaria, or unknown reactions.

area that best facilitates dependent drainage (**Figure 210-7A**). **Do not make the incision more than 1 cm in length.** Gently insert a closed curved hemostat into the incision (**Figure 210-7B**). Gently spread the jaws of the hemostat in several different directions to break up any loculations (**Figure 210-7C**). Express and suction any remaining purulence. Insert a sterile rubber drain cut from a 0.25 inch wide Penrose drain or from a sterile surgical glove (**Figure 210-7D**). **Place one to two silk sutures though the drain and the oral soft tissues. This will ensure that the drain does not fall out and result in premature closure of the incision and/or aspiration of the drain.**

The second technique for simple intraoral incision and drainage differs only in the location of the incision. Make an incision with a #15 scalpel blade at the alveolar crest within the gingival sulcus, scalloping around the teeth. Extend the incision one tooth medial and distal to the tooth in question or the area of the abscess. Gently elevate the attached gingiva from the bone with a blunt instrument. Continue the blunt dissection until the abscess cavity is penetrated. This typically occurs just within the level of unattached gingiva. The remainder of the procedure is as described above. This technique affords some mechanical advantages to the operator and is well tolerated by the patient postoperatively. It can be performed in both arches and in the buccal, palatal, and/or lingual directions. It is often useful for draining a periodontal abscess.

EXTRAORAL INCISION AND DRAINAGE

Extraoral incision and drainage is indicated when a dental infection appears to be progressing toward inevitable spontaneous extraoral drainage.¹⁵ This procedure requires more attention and skill because of the numerous underlying vital structures and the possible cosmetic consequences.^{3,15} Make every effort

to avoid extraoral incision and drainage.³ Consider consulting a Dentist or Oral Surgeon before performing an extraoral incision and drainage.

Extraoral incision and drainage differs from the intraoral approach.^{3,15,16} **Advise the patient that there will almost certainly be a visible scar after the incision heals.**^{3,15} Extraoral incision and drainage requires the use of sterile technique. Prepare the area with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a field. Perform local subcutaneous infiltrative anesthesia of the skin. Use a separate needle and syringe for any intraoral anesthetic techniques.

Make a 1.0 to 1.5 cm long incision with a #15 scalpel blade in an area of healthy skin proximal to the site of expected breakdown and in a location that facilitates dependent drainage (**Figure 210-8**). Extend the incision into the subcutaneous tissues. This is another critical difference from the intraoral technique. Insert a hemostat to penetrate and drain the abscess cavity. Spread the hemostat in several directions to break up any loculations. The remainder of the procedure is performed as described as above. Scarring with extraoral incisions is virtually universal.

PEDIATRIC CONSIDERATIONS

Facial infections in children tend to develop and progress more rapidly. They are more likely to present with systemic signs and symptoms.^{31,32} Facial infections in children are also more likely to be associated with complications such as dehydration or bacteremia.³¹ Unlike adults, the anatomic location of a facial infection in a child can be a more useful guide in determining its source and management.³¹ In general, upper facial infections tend to be more common in children less than 5 years of age and frequently have no identifiable source. Children older than 5 years of age more commonly have lower face infections and typically have an odontogenic or wound-related source.³¹ According to the American Academy of Pediatric Dentistry, a child presenting with facial swelling secondary to a dental infection should receive immediate dental attention.³³ Lastly, in sharp contrast to adults, children with facial infections in either upper or lower locations more frequently respond to antibiotics alone and may not require an incision and drainage procedure.³¹

ASSESSMENT

Basic postoperative assessment includes inspecting the operative site for those minor complications described below. **Assess adequate drain retention. A loose intraoral drain may represent an aspiration risk.** Observe the patient for postprocedural bleeding. It can be controlled with the application of pressure, injection of a local anesthetic agent containing epinephrine, or topical Gelfoam. Wound cultures are not indicated unless the patient is immunocompromised or the infection is recurrent. Wound cultures usually demonstrate mixed oral flora with no predominate organism.

AFTERCARE

The application of warm moist compresses, oral fluids, rest, and good nutrition are mainstays in the treatment of any inflammatory process. Patients may benefit from a soft bland diet and frequent oral rinses with a warm saltwater solution. All patients require postoperative oral analgesics.^{3,5,15,16} Patients with an extraoral incision require daily or twice daily dressing changes depending on the dressing soiled.^{3,5,15,16} Provide the patient with adequate supplies and education. Instruct the patient on the application of pressure if postprocedural bleeding occurs. Refer the patient to a Dentist within 24 to 48 hours.

FIGURE 210-7. Incision and drainage of a periapical abscess that has extended into a vestibular abscess. **A.** Make a stab incision with a #11 scalpel blade. **B.** Insert a hemostat into the incision. **C.** Advance the hemostat into the abscess cavity to lyse any adhesions. **D.** Place a sterile drain into the abscess cavity.

Nearly half of all Medicare patients seen in the Emergency Department for dental complaints will not follow-up with a Dentist within 6 months which may result in inadequate care overall.³⁴

The use of antibiotics in light of adequate drainage is somewhat controversial.^{8,35,36} Clear-cut indications for oral antibiotics in orofacial infections include cellulitis, extraoral incision, systemic symptoms, persistent infection, pericoronitis, fascial space involvement, and immunocompromised patients.^{4,9,15,21} The prudent Emergency Physician is advised to err on the side of caution while the academics quarrel over antibiotic indications. Penicillin is the drug of choice for the empiric treatment of dental-related infections. Alternatives to penicillin include erythromycin, clindamycin, or a cephalosporin. Clindamycin is the first alternate choice. It is especially useful when anaerobes are suspected or in recalcitrant infections where sensitivities are lacking.^{3,5,11,15}

Allow the intraoral drain to remain in place until the swelling has resolved and purulent drainage has ceased. Evaluate the patient for

drain removal or advancement in 24 to 48 hours. Prescribe oral antibiotics and analgesics during this time.

Occasional patients need to be admitted to the hospital for intravenous antibiotics.³⁵ This includes airway concerns, facial cellulitis, large abscesses, and many of the complications noted in **Table 210-2**.⁶⁻⁸ This should be done in consultation with the Dentist or Oral Surgeon and the admitting physician.

COMPLICATIONS

Minor postoperative pain, swelling, bleeding, drainage, and possibly bruising can be expected following incision and drainage of a dental abscess. Significant postprocedural bleeding can be controlled with pressure, a vasoconstricting local anesthetic agent, or topical Gelfoam.^{5,11,22,23} An incision and drainage tract that communicates freely between the oral cavity and the external face represents a significant complication. Refer these patients to a Plastic or Oral Surgeon.

FIGURE 210-8. Extraoral drainage of a dental abscess. Choose a location that has healthy skin and that will allow dependent drainage.

SUMMARY

The recognition of common dental-related infections (i.e., pericoronitis, periodontal abscesses, and dental abscesses) can impact patient prognosis and morbidity. The diagnosis and treatment of these maladies, and their complications, requires knowledge of dental anatomy and pathophysiology. The Emergency Department management of these infections is quick and simple. Refer all patients to a Dentist or Oral Surgeon for timely definitive dental care.

Post-Extraction Pain and Dry Socket (Alveolar Osteitis) Management

Eric F. Reichman

INTRODUCTION

Post-extraction pain, or periosteitis, begins as the local anesthetic agent wears off. The pain begins to diminish, most of the time, within 12 hours. The prescription of nonsteroidal anti-inflammatory drugs will provide analgesia and comfort while the pain subsides over 1 to 2 days. Narcotic analgesics may occasionally be required for the first 24 to 48 hours.

Pain that develops 2 to 4 days after the tooth extraction most likely indicates a localized alveolar osteitis or a dry socket. A dry socket occurs most commonly with the extraction of the third mandibular molar but can be associated with any tooth that has been extracted. The pain is quite severe in nature and is localized to the area of the extraction site. The extraction site may emit a foul odor and the patient often complains of a bad taste in their mouth.^{1,2} Physical examination may reveal the socket is missing a clot but this is sometimes difficult to identify. The signs of an infection are absent.

There has been much work in the prevention of a dry socket.³⁻⁸ This prevention focuses on methods in surgical technique and injections that occur at the time of tooth extraction. These methods are not in widespread use yet. Despite these methods, patients still present to the Emergency Department with a dry socket. The Emergency Physician must know how to solve this simple condition.

ANATOMY AND PATHOPHYSIOLOGY

The exact etiology or the pathogenesis of a dry socket is not clear.^{1,2,9-12} It may be multifactorial due to smoking, a localized infection, a poor blood supply, traumatic extractions, a foreign body in the socket, and certain medications. These factors result in an increased level of fibrinolysis of the blood clot in the socket before the clot has had the time to be replaced by granulation tissue. The clot falls out of the socket and exposes the bony surface of the socket to the oral cavity. The exposed bone is extremely sensitive to air resulting in severe pain.^{1,2,9,10}

INDICATIONS

The single and utmost therapeutic goal of alveolar osteitis is to relieve the patient's pain during the healing process. This procedure should be performed on all patients with a dry socket.

CONTRAINDICATIONS

There are no contraindications to the management of a dry socket.

EQUIPMENT

- Dental mirror
- 2×2 gauze squares
- Scissors
- Dry socket paste or Dressol-x
- Gelfoam
- Irrigating syringe
- Normal saline solution
- Frazier suction catheter
- Suction source and tubing

- Forceps
- Iodoform ribbon gauze
- Zinc oxide eugenol (ZOE)-impregnated ribbon gauze
- Oil of cloves
- Tranexamic acid
- Neocone (not approved or available in the United States)
- Alvogyl (eugenol, iodoform, and butamen)

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare to the patient and/or their representative. A signed consent is not required for this procedure. Place the patient sitting upright or reclining. A multipositional dental chair is ideal and allows for a variety of positions to visualize the affected tooth. This procedure may be accomplished with no anesthesia. Some may consider performing a dental block to temporarily alleviate the patient's pain, allow the procedure to be accomplished with minimal discomfort, and increase the level of patient satisfaction. If performed, use lidocaine without epinephrine because the procedure is quickly performed and the anesthesia wears off while the patient is still in the Emergency Department. Refer to Chapter 209 for the complete details regarding dental anesthesia and analgesia. Consider obtaining a plain radiograph or Panorex to rule out a retained root tip or foreign material in the socket.

TECHNIQUES

Identify the defective tooth. Gently and thoroughly irrigate the socket with warm normal saline and low-level suction to remove any debris.^{13,14} Use a forceps to pack dry socket paste into the socket. Dry socket paste is composed of balsa wood fragments saturated with eucalyptol and looks like chewing tobacco. Completely fill the socket with the dry socket paste. The patient will experience almost instant pain relief if a dental block was not performed. Place a piece of Gelfoam on top of the dry socket paste. Compress the Gelfoam and dry socket paste into the socket. Instruct the patient to bite down against a 2×2 gauze square placed over the socket for 5 to 10 minutes. Dressol-x may be used instead of dry socket paste if available.

ALTERNATIVE TECHNIQUES

Unfortunately, few Emergency Departments stock dry socket paste or Dressol-x. An alternative is ribbon gauze or Gelfoam impregnated with eugenol, iodine, or oil of cloves.^{13,14} Ribbon gauze tends to dry out and fall out sooner than commercially available dry socket paste. Use a forceps to pack the socket completely with the impregnated ribbon gauze (**Figures 211-1A, 211-1B, and 211-1C**) or Gelfoam. Place a piece of plain Gelfoam on top of the socket (**Figure 211-1D**). Compress the plain Gelfoam and the underlying impregnated ribbon gauze or impregnated Gelfoam into the socket. Instruct the patient to bite down against a 2×2 gauze square placed over the socket for 5 to 10 minutes. Place a figure-of-eight stitch through the soft tissue and over the packed socket to prevent the Gelfoam from falling out (**Figure 211-2**).

There are several other successful techniques described in the literature to manage the patient who presents with a dry socket.^{3,8,14-16} These techniques are also used immediately after extraction of the tooth. These include Oraquix gel (2.5% prilocaine, 2.5% lidocaine thermosetting agents, hydrochloric acid, and purified water), low-level laser treatment (LLLT), the SaliCept patch derived from aloe vera, and vitamin C.¹⁴ Plasma-rich growth factors (platelets,

FIGURE 211-1. Packing a dry socket with ribbon gauze. **A.** The empty socket. **B.** Pack the socket starting inferiorly and working upward. **C.** Completely fill the socket. **D.** Apply Gelfoam over the socket and the ribbon gauze.

fibrogen, platelet-derived growth factor, and tissue growth factor) and G.E.C.B. pastille (3% guaiacol, 3% eugenol, chlorobutanol, and balsam peru) have been placed in the empty socket.⁸ Neocone was compared to Alvogyl and zinc oxide eugenol (ZOE).¹⁵ All three relieved the pain of a dry socket. Neocone resulted in faster healing. Neocone is not U.S. Food and Drug Administration approved for availability in the United States. A honey-coated dressing has been packed in a pocket.¹⁶ This dressing halts necrosis, prevents infection, tastes good, and has no adverse effects. Soak Gelfoam in 160 mg of tranexamic acid. Pack the Gelfoam into the socket and secured with a stitch (**Figure 211-2**).³ Only the use of tranexamic acid is feasible in the Emergency Department.

ASSESSMENT

The patient should experience almost immediate pain relief after the socket is packed. If a dental block was performed, allow the local anesthetic to wear off to ensure the patient's pain truly has resolved.

AFTERCARE

The patient may be discharged immediately after the procedure or after the local anesthetic has worn off. Nonsteroidal anti-inflammatory drugs are usually adequate to provide analgesia. Narcotic analgesics are not needed or required. Arrange follow-up as soon as possible with the Dentist or Oral Surgeon who performed the extraction

FIGURE 211-2. The figure-of-eight stitch over a packed dry socket.

procedure. The dressing must be replaced daily, or as needed, until the patient is pain free. Instruct the patient to begin a soft diet, to not ingest extremely hot or cold substances, and to not play with the packing with their tongue. **Instruct the patient to also not suck anything, use a straw, gargle, spit, or smoke.** All these activities will produce negative pressure within the oral cavity and remove the clot from the extraction site.⁸

The decision to prescribe antibiotics to cover the oral flora is physician dependent. There is no literature to support or refute this practice. Consult the Dentist or Oral Surgeon who extracted the tooth. Oral penicillin VK (500 mg four times a day) is the preferred antibiotic if they are prescribed. Clindamycin (300 mg four times a day) is an alternative for patients allergic or intolerant to penicillin.

COMPLICATIONS

There are no complications associated with this procedure. A potential complication is the aspiration of the material used to pack the socket. This has never been reported in the literature. The packing may fall out and result in the patient's pain recurring. Instruct the patient to return to the Emergency Department if the packing falls out prior to their follow-up appointment.

SUMMARY

A dry socket can be extremely painful. Packing an empty socket is easy, quick, simple, and provides the patient with significant relief. The packing needs to be changed every 24 to 48 hours for several days and then less frequently after that until the patient is free of pain. Consider prescribing antibiotics to cover oral flora and analgesics to manage pain in consultation with the Dentist or Oral Surgeon who extracted the tooth.

Post-Extraction Bleeding Management

Eric F. Reichman

INTRODUCTION

Post-extraction bleeding is a common problem after the removal or extraction of a tooth. It is often seen in the Emergency Department in the late evening or night when the patient is unable to contact their Dentist. Bleeding that occurs within a few hours of the extraction is often due to the wearing off of the vasoconstrictor effect of the local anesthetic solution used for anesthesia.¹ The application of direct pressure over the bleeding site by having the patient bite down on a folded piece of moist gauze almost always controls post-extraction bleeding.¹ Many patients, however, will report that they have been doing this prior to coming to the Emergency Department and require additional assistance. Post-extraction bleeding can be classified depending on when it occurs (Table 212-1).

ANATOMY AND PATHOPHYSIOLOGY

A careful history may reveal that the patient inadvertently caused the extraction site to bleed by drinking through a straw, spitting, gargling, or smoking. All these activities will produce negative pressure within the oral cavity and remove the clot from the extraction site. Ask the patient if they are touching the extraction site with their tongue causing a mechanical disruption of the clot. Obtain information about any significant medical history, any history of bleeding, and current medications. This includes use of aspirin products, anticoagulants, broad-spectrum antibiotics, alcohol, and antineoplastic medications. These all may contribute to prolonged bleeding. Ask about the symptoms and examine for the signs of liver disease, hypertension, or hematologic disorders.^{2,3} Post-extraction bleeding may be a sign of an underlying coagulopathy due to anticoagulant use, clotting factor disorders, thrombocytopenia, or vascular abnormalities.¹

INDICATIONS

All post-extraction bleeding must be managed carefully and methodically. The techniques are easy to perform, simple, and straightforward.

TABLE 212-1 Types of Post-Extraction Hemorrhage

Type	Timing	Most likely etiologies
Primary	At time of extraction	Blood vessels Bone Tissue damage
Reactionary	2–3 hours after extraction	Loss of vasoconstriction from local anesthetic solution wearing off
Secondary	Days 1–14 after the extraction	Dry socket Infection

Modified from McCormick et al.¹

CONTRAINDICATIONS

There are no contraindications to the management of post-extraction bleeding.

EQUIPMENT

- 2×2 gauze squares
- Irrigating syringe
- Dental mirror, optional
- Local anesthetic solution containing 1:100,000 epinephrine
- 23 to 25 gauge, 1.5 inch needle
- 5 mL syringe
- Silk, plain gut, or Vicryl sutures, 3–0 on a half-circle needle
- Absorbable gelatin sponge (Gelfoam)
- Oxidized regenerated cellulose (Surgicel)
- Topical thrombin
- Topical collagen
- Tranexamic acid
- Ankaferd Blood Stopper
- Hemocoagulase (Reptilase)
- Silver nitrate matchsticks
- Suture set
- Dental forceps
- Tea bag
- Bone rongeur
- Bone wax (beeswax, paraffin, and a softening agent)
- Headlamp
- Yankauer suction catheter
- Suction source and tubing
- Electrocautery unit

PATIENT PREPARATION

Explain the risks, benefits, potential complications, and aftercare to the patient and/or their representative. Document this discussion in the medical record. A signed consent form is usually not required for these procedures. Consider obtaining a radiograph of the affected area to rule out a retained root or a bony spur.

Position the patient to visualize the extraction site. Place the patient in a multipositional dental chair, if available, or on a gurney. Do not place the patient in a chair as they may become presyncopal and require being placed supine to prevent injury. An overhead light source or a headlamp is ideal to illuminate the field. Suction any blood and oral secretions from the mouth. Visualize the extraction site for any signs of bleeding. Thoroughly irrigate the site with warm saline and remove all clots with the aid of suction. It may be necessary to perform a dental block if the patient complains of pain upon irrigation. Refer to Chapter 209 for the complete details regarding dental anesthesia and analgesia.

TECHNIQUES

The management of post-extraction bleeding is simple. Numerous methods to control the bleeding have been described and tested (Figure 212-1, Tables 212-1 and 212-2). These techniques are often performed in a sequential manner as described below. The techniques may, of course, be performed in any order depending on the physical examination and physician preference.

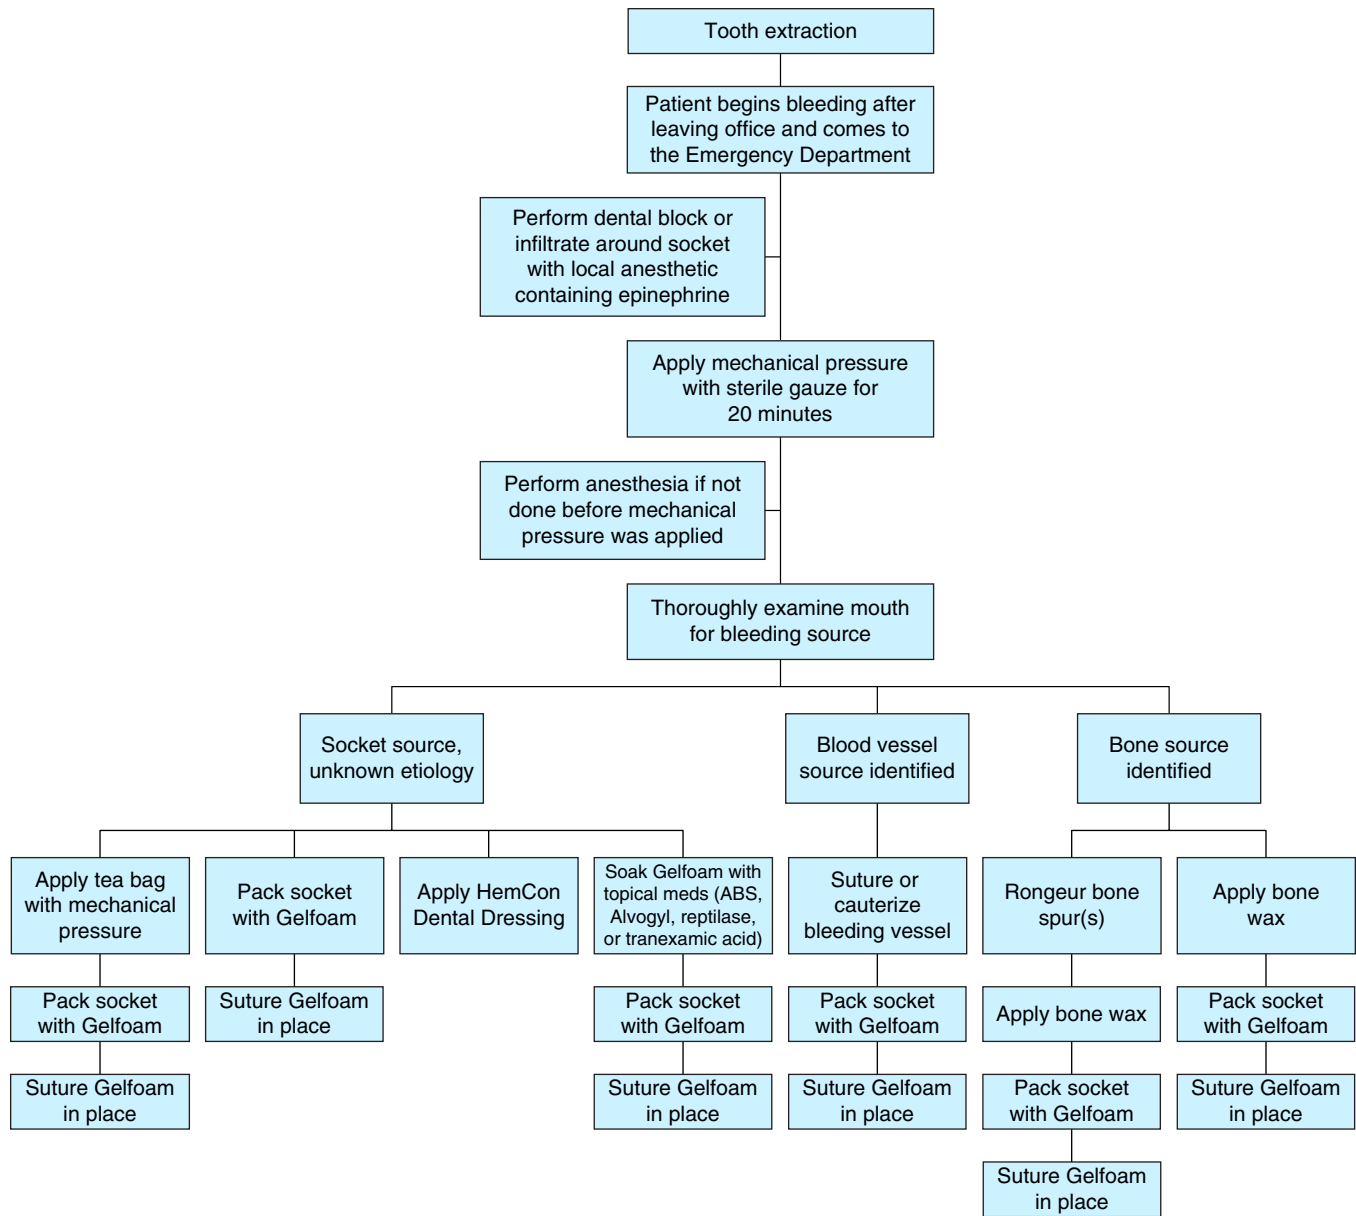

FIGURE 212-1. Treatment algorithm.

TABLE 212-2	Methods to Control Post-Extraction Bleeding
	Absorbable dressing into socket and mechanical pressure with gauze squares
	Absorbable dressing into socket and stitch gingival tissue closed
	Ankaferd Blood Stopper
	Bone wax to bone spurs
	Cauterize bleeding granulation tissue
	Cauterize or stitch bleeding blood vessels
	Gelfoam
	Gingival infiltration with local anesthetic containing epinephrine
	HemCon Dental Dressing
	Hemocoagulase (reptilase)
	Mechanical pressure with gauze squares
	Moist tea bag and pressure
	Rongeur followed by bone wax to bone spurs
	Stitch gingival tears
	Surgicel
	Topical collagen
	Topical thrombin
	Topical tranexamic acid

MECHANICAL PRESSURE

Place saline-moistened 2×2 gauze squares over the socket. Instruct the patient to apply firm pressure by biting down on the gauze for 20 minutes.¹ Instruct the patient to maintain pressure for 20 minutes despite initial bleeding. Place the suction catheter intermittently into the vestibule of the patient’s mouth to remove any blood and secretions. Allow the patient to self-suction during the 20 minutes they are biting down on the gauze. Show the patient the proper way to use the suction prior to leaving the examination room. The application of pressure will control most post-extraction bleeding. It may be necessary to perform a dental block, if not performed during the irrigation phase, if the patient cannot bite down due to pain.

TEA BAG APPLICATION

Place a saline-moistened tea bag in the socket if mechanical pressure does not control the bleeding.⁴ The tannins in the tea leaves will assist with the coagulation process. Instruct the patient to bite down on the tea bag for 15 minutes. Place the suction catheter

intermittently into the vestibule of the patient's mouth to remove any blood and secretions. Allow the patient to self-suction during the 20 minutes they are biting down on the gauze. Show the patient the proper way to use the suction prior to leaving the examination room.

ABSORBABLE DRESSINGS

The two most commonly used absorbable dressings are Gelfoam and Surgicel. Gelfoam is an absorbable gelatin sponge that is readily available and inexpensive. It forms a scaffold for the formation of a blood clot. Surgicel is composed of oxidized and regenerated cellulose. It promotes coagulation better than Gelfoam and can be packed into the socket under pressure. Unfortunately, Surgicel results in delayed healing of the socket and its use should be reserved for persistent bleeding or when Gelfoam is not available.

Place an absorbable dressing (Gelfoam or Surgicel) in the socket if the extraction site continues to bleed.²⁻⁴ The author prefers to use Gelfoam because it is easier to manipulate and it is absorbed more rapidly than Surgicel. Work the Gelfoam in your fingers until it resembles the shape of the socket. Insert the Gelfoam into the socket and compact it with a dental forceps. Insert additional pieces of Gelfoam into the socket, as necessary, to obtain a solid mass of Gelfoam filling the socket. An alternative is to pack the socket with Surgicel. Once the socket is packed, apply a 2×2 gauze square over the socket. Instruct the patient to bite down for approximately 20 to 30 minutes. Place the suction catheter intermittently into the vestibule of the patient's mouth to remove any blood and secretions. Allow the patient to self-suction during the 20 minutes they are biting down on the gauze. Show the patient the proper way to use the suction prior to leaving the examination room.

The author prefers to place a figure-of-eight stitch using 3–0 silk suture, plain gut suture, or Vicryl suture over the socket (Figure 212-2). The suture applies pressure over the socket and ensures that the Gelfoam or Surgicel will not prematurely fall out of the socket. This technique will usually stop most post-extraction bleeding.

Two additional absorbable dressings are topical thrombin and collagen. They are expensive, not usually available in the Emergency Department, and their use should be limited to circumstances where other hemostasis methods have failed. Topical thrombin is made from bovine thrombin. Place a piece of Gelfoam or Surgicel saturated with thrombin into the socket. Thrombin converts fibrinogen to fibrin, bypassing the coagulation cascade, to form a clot within the socket. Collagen is available in multiple forms from a variety of sources. It promotes platelet aggregation and forms a scaffold for the formation of a clot. Pack the socket with collagen and cover it with a piece of Gelfoam. Place a figure-of-eight suture over the thrombin or collagen filled socket to secure it in place.

FIGURE 212-2. Pack the socket with Gelfoam followed by a figure-of-eight stitch to control the bleeding.

The use of chitosan bandages to control battlefield and prehospital hemorrhage has crossed over into the dental realm. Chitosan dental bandages, also known as HemCon Dental Dressing (HemCon Medical Technologies, Portland, OR), have been designed to control post-extraction hemorrhage (Figure 212-3). Chitosan is a naturally occurring polysaccharide derived from shellfish. It attracts red blood cells. When placed over the bleeding extraction site, the

A

B

FIGURE 212-3. The HemCon Dental Dressing. **A.** The dressing. **B.** The dressing placed in a bleeding tooth socket. (Photos courtesy of HemCon Medical Technologies.)

red blood cells attach to the bandage to form a clot and tamponade the bleeding.

LOCAL ANESTHETIC INFILTRATION

Infiltrate the soft tissue surrounding the socket with local anesthetic solution containing epinephrine if the bleeding is not controlled by the above methods. The most commonly used local anesthetic solutions are lidocaine and bupivacaine. Infiltrate the soft tissues surrounding the socket with the local anesthetic solution until the tissue blanches. This usually requires 2 to 3 mL of the local anesthetic solution. Irrigate the socket. Apply a piece of moist gauze over the socket. Instruct the patient to bite down and to exert pressure on the socket. The patient is often able to bite down much harder on the tissues after the infiltration of the local anesthetic solution. Place the suction catheter intermittently into the vestibule of the patient's mouth to remove any blood and secretions. Allow the patient to self-suction during the 20 minutes they are biting down on the gauze. Show the patient the proper way to use the suction prior to leaving the examination room.

The effect of mechanical pressure combined with the vasoconstrictive effects of epinephrine control the bleeding. Occasionally, after the vasoconstrictive effect of epinephrine wears off, there is a rebound effect and the persistence of bleeding. This may be prevented by routinely placing Gelfoam or Surgicel into the socket after the bleeding is controlled.

ANKAFERD BLOOD STOPPER

Ankaferd Blood Stopper or ABS (Ankaferd Health Products, Istanbul, Turkey) is an extract of five plants. It was developed by Huseyin Cahit Firat, a Turkish entrepreneur and an economist with an interest in herbology. It is available in a spray, liquid ampule, and pad form. ABS induces the rapid formation of a protein network structure that acts as an anchor for erythrocyte aggregation. It is independent of the coagulation cascade and works with defects in the coagulation cascade and platelet abnormalities.⁵ It is ideal for patients with a coagulopathy. It is approved by the Turkish Ministry of Health and used both prehospital in ambulances and hospitals. It is applied by soaking Gelfoam with the ABS and packing the socket.

TRANEXAMIC ACID

Tranexamic acid, or TXA, is used for traumatic bleeding, hyphemas, subdural and intracranial hemorrhage, epistaxis, and menstrual bleeding to name a few of its uses. TXA is a synthetic analog of the amino acid lysine. It has the desirable properties of being an antifibrinolytic. TXA has been used for post-extraction bleeding prior to the extraction intravenously, topically as a mouthwash prior to or after the extraction, or for dental surgery in hemophiliacs.⁶⁻¹⁰ Dissolve a 650 mg tablet in 20 mL of sterile water to make a 3.25% mouthwash solution. Instruct the patient to swish and swallow four times a day. One can also dissolve a 500 mg tablet in 20 mL of sterile water to make a more dilute mouthwash. As an alternative, mix 1 gm per 10 mL of the intravenous formulation of TXA with 10 mL of sterile water to make a 5% mouthwash solution. It can also be applied by soaking Gelfoam with the TXA and packing the socket.

HEMOCOAGULASE (REPTILASE)

The reptilase time (RT) is a blood test used to detect deficiency or abnormalities in fibrinogen. Reptilase is an enzyme found in the venom of *Bothrops* snakes. It has an activity similar to thrombin. Reptilase is resistant to inhibition by antithrombin III unlike thrombin. Reptilase also differs from thrombin by releasing fibrinopeptide

A but not fibrinopeptide B in its cleavage of fibrinogen to form fibrin. It is applied by soaking Gelfoam with the hemocoagulase and packing the socket.¹¹

MISCELLANEOUS TECHNIQUES

Reexamine the extraction site if the bleeding is not controlled by the above methods. The source of bleeding may be new granulation tissue, gingival tears, a bone spur, or a partially transected vessel. Cauterization of granulation tissue with silver nitrate or electrocautery will control the bleeding. Hand-held, disposable, single patient use electrocautery units work well but require the patient to be anesthetized. Use a blunt instrument to feel for the presence of a bone spur. This may be a source of significant bleeding. Remove the bone spur with a rongeur or cover it with bone wax to control the bleeding. Cover the bone wax with Gelfoam and suture it in place. An exposed and bleeding arteriole or venule can be controlled with cauterization (i.e., silver nitrate or electrocautery) or the application of a plain gut suture through the vessel. Suture any tears in the gingiva.

ASSESSMENT

Observe the patient for 30 to 60 minutes after the bleeding has terminated. Do not give the patient anything by mouth (NPO). Reevaluate the socket for signs of bleeding. Continued bleeding requires further attempts at termination.

AFTERCARE

Discharge the patient home after the bleeding has been terminated and a brief observation period. **Instruct the patient to avoid any liquids or solids for 2 hours and rinsing their mouth for 24 hours. Stress the importance of not spitting, gargling, drinking through a straw, smoking, using aspirin-containing products, or playing with the site with their tongue.** Instruct the patient to apply gauze squares and bite down for 20 minutes if the bleeding returns. They should return promptly to the Emergency Department if the bleeding continues after 20 minutes. Additional instructions should include a soft diet for 24 hours, avoidance of extremely hot or cold substances, avoidance of chewing gum, avoidance of other such "sticky" foods, and minimization of physical activity for 24 hours. The patient may clean (brush and floss) teeth as normal except those teeth immediately adjacent to the extraction site. Arrange follow-up as soon as possible with the Dentist or Oral Surgeon who performed the extraction.

COMPLICATIONS

There are no documented complications associated with the termination of post-extraction bleeding. The complications are associated with the bleeding itself. Obtain screening labs (e.g., prothrombin time, partial thromboplastin time, platelet count, and bleeding times) if hemostasis is not achieved by any of the aforementioned methods. Early consultation with a Dentist or Oral Surgeon and a Hematologist should be considered if the patient is coagulopathic or has a bleeding disorder.

SUMMARY

A careful history and physical examination will often provide the reasons for most post-extraction bleeding that presents to the Emergency Department. Most patients without complicating medical conditions will be easily managed in a simple and systematic manner with a minimal amount of equipment (**Figure 212-1**). All patients should follow-up with their Dentist or Oral Surgeon after the bleeding is terminated.

Defective Dental Restoration Management

Richard Dean Robinson and Daisha McLarty

INTRODUCTION

The field of restorative dentistry is a complex specialty that derives from many disciplines. Patients have often invested considerable time, money, and quite possibly “blood, sweat, and tears” in their dental work. This may be particularly true with the advent of both cosmetic and implant dentistry which involve long and complicated treatment plans that are often not covered by insurance. A patient’s investment in their dental work and the technical complexity of today’s dental appliances should not be taken lightly. In fact, the treatment of common dental emergencies was published in the *Emergency Medicine Clinics of North America* under the heading “Difficult and Advanced Procedures.”¹

The urgent management of an acutely problematic dental restoration can be as simple as relieving discomfort, treating injury and infection, and employing temporizing measures until definitive treatment can be rendered by the appropriate specialist. This requires a basic understanding of dental anatomy, the pathophysiology of various dental states, and their typical treatment modalities.^{1,2} It goes without saying that one should also recognize the inherent and all too frequent limitations of treating these problems in the Emergency Department. **The key to the successful emergent or urgent management of an acutely problematic defective dental restoration is stabilization and timely referral with great care to “first, do no harm.”**

A few basic principles serve as a useful guide in treating patients with defective dental restorations. First, know your limitations. Dental pain in general, and a defective dental restoration in particular, is rarely if ever a true emergency.²⁻⁴ Chronic problems should be treated with equal measures of conservatism and reluctance. Refer the patient to a Dentist if you are hesitant to treat or are unfamiliar with an appliance or a presentation. Always consider a secondary or comorbid process. Consider the utility of dental radiographs when in doubt. Never remove a fixed appliance without first discussing it with a specialist, preferably the one who placed it. Save anything and everything that belongs to the patient, whether it be appliance or tissue, as it may have utility for the definitive treatment process.^{5,6} Treat pain, inflammation, and evidence of infection. Consider a reversible or temporary solution over all others. Remember to appropriately treat a traumatized (e.g., fracture, luxation, or subluxation) dental restoration when the situation presents. Always consider ingestion or aspiration when dealing with a multiply fragmented tooth or appliance. Consider facial, neck, chest, and abdominal radiographs in cases where all dental fragments cannot be accounted.^{5,7-10} Whenever a patient is actively involved in an ongoing treatment process, it is probably best to do as little as possible. Always use caution and tact when discussing the possibility of a defective dental restoration with a patient. Remember that you are not an expert. The treating specialist may have insight into the patient’s current condition of which you are unaware. Attempt to consult before treating. Always arrange follow-up within 24 to 48 hours.

ANATOMY AND PATHOPHYSIOLOGY

Patients frequently present to the Emergency Department with some sort of dental complaint and their primary concern is typically pain related.^{1,2,11,12} The perioral tissues are exceptionally sensitive to noxious stimuli. This is particularly true for the oral mucosa, periodontal ligament, dentin, and pulp. This concept is paramount to the effective management of any dental-related complaint. Although a patient’s chief complaint may be directed at a particular tooth, be diligent in searching the entire mouth for alternative primary, comorbid, or secondary problems.

A meaningful discussion of the management of defective dental restorations requires a brief outline of the available types of dental appliances. In general, dental appliances are either fixed or removable. Fixed dental appliances are considered permanently attached to the teeth. They include crowns, bridges, implants, some forms of dentures, orthodontic bands and brackets, interdental wiring, and any type of filling (e.g., silver amalgam, gold, porcelain, or tooth-colored composite material). Removable dental appliances are those that are not permanently attached to the teeth and include partial dentures, complete dentures, space-maintenance devices, and other orthodontic devices.

Understanding whether a defective dental device is permanent or removable is often the first step in managing an acutely problematic appliance. Detaching a broken or defective removable appliance is a simple and easy solution if it can be done safely and without significantly damaging the appliance. If removal would significantly alter or damage an appliance and there is no other reasonable option but to remove it, document the discussion with the patient and their consent to proceed. This is true whether the appliance is permanent or removable.

Removable dental appliances can predispose patients to several easily treatable mucosal conditions such as ulcerations, abrasions, or mucosal infections.¹³⁻¹⁵ Compromised cellular immunity, broad-spectrum antibiotics, low salivary flow, poor oral hygiene, and trauma from poorly fitting dentures can all contribute to oral *Candida* overgrowth.^{13,16} Patients often complain of burning

pain. Treat the affected oral mucosa with nystatin or clotrimazole troches. The appliance itself may harbor the organism and must be treated. Instruct the patient to take the appliance out of their mouth for 24 to 48 hours and soak it overnight in a nystatin suspension (5 mL nystatin in 250 mL [8 ounces] of tap water). Instruct the patient to scrub the denture daily with an approved product to clean it.¹³⁻¹⁵

Oral candidiasis must be differentiated from other mucosal ulcerating conditions such as simple traumatic ulcers, aphthous ulcers, and oral herpes. Herpetic lesions occur on attached mucosa only whereas aphthous ulcers occur on unattached mucosa.¹³⁻¹⁶ Traumatic ulcers, minor aphthae, and major aphthae can be treated with topical corticosteroid ointment, such as triamcinolone, applied with a cotton-tipped applicator. The symptoms associated with herpetic outbreaks can be diminished if treated with an antiviral agent.¹³⁻¹⁵ Orthodontic or interdental wiring that is impinging upon the oral mucosa may lead to traumatic ulcerations. Apply soft dental wax directly to the irritating appliance to relieve the impingement. This can be easily removed or replaced and is available over the counter at many local pharmacies.

In general, all patients with painful mucosal conditions may benefit from soft and bland diets, frequent use of ice chips for discomfort, and frequent warm saltwater rinses to avoid superinfection.^{13,14} A stomatitis cocktail or BMX solution may be helpful for patients with severe mucosal pain. Mix equal amounts of Benadryl (12.5 mg/5 mL), Maalox, and Xylocaine (2% viscous lidocaine). Instruct the patient to swish 30 mL in their mouth for 1 minute and then spit it out. **Instruct the patient not to swallow so they will not get anticholinergic or local anesthetic toxicity.**

The repair of broken or defective removable appliances in the Emergency Department is not recommended even though multiple over-the-counter products are available for home use (Figure 213-1).¹⁶ Under the best of circumstances these procedures can be tedious, time consuming, and fraught with complications, even for the trained dental professional.³ Most importantly, a substandard repair attempt can result in patient discomfort, morbidity, and irreversible damage to an otherwise salvageable appliance. **In this light, it seems best to simply recommend removal and a dental referral to the patient seeking care for a broken removable appliance.**¹⁶ Although far less than ideal, a home repair kit may be a viable option for some patients under certain circumstances.

The temporary urgent repair of defective fixed dental restorations by nondental personnel is advocated throughout the literature.^{2,3,11,12,14,17-19} Use caution, however, when evaluating a new or recently placed fixed restoration because sensitivity from recent dental procedures can occur due to pulp or periodontal ligament (PDL) irritation.²⁰ This may be a normal and expected sequela of the dental procedure and not necessarily an indication that the restoration is defective.^{1,20,21} Trauma from occlusion can result if a new dental restoration is left “too high” and does not fit properly with the opposing dentition.^{3,14,18-20} These patients complain of pain with mastication and are sensitive to percussion secondary to PDL irritation. **Do not alter a fixed restoration if it is firmly in place.** Simple temporizing measures include dental blocks (Chapter 209), oral analgesics, a soft diet, and possibly removing the tooth from occlusion by placing a small amount of soft dental wax (or something similar) between the teeth on the opposite side.³

Long-standing fixed dental restorations may be defective secondary to microleakage or recurrent decay around the margins of the restoration.^{1,20} Estimates suggest that approximately one in three restorations in existence may be defective in some fashion.^{20,21} A faulty restoration that sits within or upon a tooth can lead to dentin exposure regardless of the etiology. Exposed dentin is highly sensitive and prone to further decay. Dentin sensitivity (also known as reversible pulpitis) is typically nonspontaneous and fleeting.^{1,16,18,22} Patients who complain of spontaneous and lasting sensitivity have an irreversible pulpitis that is most likely due to recurrent decay. Sensitivity to percussion is indicative of periapical involvement and suggests the possibility of periapical periodontitis or an abscess.^{1,14,16,18,22}

Evaluate the tooth and its restoration for recurrent decay or possible dentin exposure if a patient presents complaining of sensitivity associated with a tooth that has a long-standing restoration. **A temporary restoration can easily be fabricated in the Emergency Department if the restoration in question is missing, broken, or easily removed.**

Consideration should be given to possible pulp pathology, as outlined above, if a restoration is firmly in place. Provide dental anesthesia, oral analgesics, antibiotics as necessary, and referral to a Dentist. Refer to Chapter 210 for details regarding the management of dental abscesses.

FIGURE 213-1. Some of the commercially available home repair kits for the fractured denture.

INDICATIONS

Replace any previously fixed, permanent or temporary, dental restoration that has completely or partially fallen out or that is easily removed with a dental explorer. Replace any previously fixed, permanent or temporary, crown that has fallen out or is easily removed with a dental explorer and is in the patient's possession.

CONTRAINDICATIONS

Relative contraindications for the placement of a temporary dental filling, or temporarily recementing a crown, include patients who are involved with extensive ongoing dental treatment plans, have a consulting specialist readily available, are at a significant aspiration risk, or have obvious extensive comorbid or secondary processes including antecedent trauma.

EQUIPMENT

- 10 mL syringe
- 18 gauge angiocatheter
- Normal saline solution
- Local anesthetic solution containing epinephrine
- Dental mirror
- Dental explorer
- 2×2 gauze squares
- Sterile cotton rolls
- Dental floss
- Clear nail polish
- Cavit-G
- IRM (zinc oxide and eugenol)
- Dycal (calcium hydroxide paste)
- Copalite (cavity varnish) or clear acrylic nail polish
- Tin foil
- Cotton-tipped applicators
- Discoid-cleoid dental carver
- Articulating paper
- Fraser suction catheters
- Suction source and tubing
- Petrolatum-based lubricant (Vaseline)
- Good overhead lighting or a headlamp

PATIENT PREPARATION

Explain the procedure, its risks, complications, and aftercare to the patient and/or their representative. Obtain an informed consent for the procedure. The simple placement of a temporary filling does not usually require local anesthesia. However, consider the use of a dental block (Chapter 209) if the patient is uncomfortable.

Prepare the patient. Seat the patient in a multipositional procedure chair. Gently irrigate the area with a syringe that contains warm normal saline and is armed with an 18 gauge angiocatheter to remove any food debris. Warm saline is usually less sensitive to the exposed dentin.¹ Gently remove any debris with a dental explorer that does not irrigate away. **Do not attempt to remove any decay because doing so may lead to a complicating pulp exposure.¹** Remove the loose portion of the restoration. **Do not remove any firmly fixed portion of the restoration.**

It is mandatory to have a dry field when performing this procedure. Dry the area to be filled with sterile cotton pellets or

compressed air. Remember that the tooth may be sensitive. A nasal cannula was successfully used as an alternative by some to keep an area dry that was constantly oozing blood. Aim the nasal cannula at a flow rate of 10 to 15 L of air or oxygen at the site prior to and during the procedure to keep the area dry. If the flow interferes with the procedure, intermittently use the nasal cannula to dry the area.

TECHNIQUES

REPLACING A TEMPORARY OR PERMANENT FILLING

Treatment of defective fillings depends upon the relative size of the defect. There are no specific guidelines of what size (i.e., how many millimeters) the defect must be to perform each of these techniques. Paint small dentin exposures with calcium hydroxide paste followed by cavity varnish or clear acrylic nail polish to relieve sensitivity.^{1,10,14,19} Alternatively, place a simple tin foil dressing over the tooth to act as a bandage following placement of the calcium hydroxide paste.^{10,14,19}

Larger defects require a filling to avoid food impaction and other sequelae. Cavit-G is an excellent choice for temporary filling material, especially in inexperienced hands.^{1,10,12,23} This material is premixed, nonirritating, and sets in approximately 30 minutes upon contact with saliva. IRM, or a mixture of zinc oxide and eugenol, is similar material with the benefit of pulp sedative properties. The use of IRM is operator dependent and requires a longer setting time.²³ Oddly enough, multiple mixtures of zinc oxide and eugenol are available over-the-counter for home use (e.g., Dentemp, Tempanol, Thin Set; **Figure 213-2**).

Cavit-G is recommended for Emergency Department use. Determine whether the missing filling exposes an open previous endodontic repair (i.e., root canal). Place a small sterile cotton pellet into the canal prior to placing the filling material if the pulp cavity is exposed.²³ Express a small amount of Cavit-G from the container. Apply it onto the cavity and condense it into the cavity with the moistened end of a cotton-tipped applicator or a dental explorer (**Figure 213-3A**). **A temporary restoration placed by nondental personnel is always better “short” and out of occlusion with the opposing tooth for patient comfort. Work quickly because Cavit-G can set rapidly and it may be difficult to remove once it sets.** Remove any excess Cavit-G with the stick end of the cotton-tipped applicator. Instruct the patient to fully occlude on the new restoration and grind their teeth back and forth in all directions for 5 to 10 minutes. This will form the occlusal aspect of the filling to fit the opposing teeth if it is not made “short.”

Cyanoacrylate is used in the Emergency Department for wound repair and has the additional properties of being hemostatic and bacteriostatic.^{24,25} Cyanoacrylate also has many applications in periodontics. It can be used as a desensitizing agent, for pulp capping, pit and fissure sealant, to seal dentin, for retrofilling material in endodontic surgeries, and to replace avulsed teeth. Some patients have used cyanoacrylate to fix their own dentures, especially dental prostheses composed of an acrylic base. Cases have also been reported of cyanoacrylate being used to repair fractured molar teeth.²⁴⁻²⁶

Using cyanoacrylate to fill a tooth is similar to using dental cement as noted above. Once the cavity is prepared and dried, drip the cyanoacrylate into the cavity until filled. Ensure there are no air bubbles. Use smoothing equipment to quickly smooth out the filling. Cyanoacrylate dries very quickly. Instruct the patient to occlude the teeth and grind similar to the above instructions.²⁶

There is some concern that cyanoacrylate may be harmful to the oral mucosa. Documented effects include urticarial reaction and skin irritation. Rarely, its vapors have been noted to induce asthma.

FIGURE 213-2. Some of the commercially available home use products for temporary dental filling and crown restoration.

Avoid unnecessary direct skin contact and use cyanoacrylate in rooms with ventilation.²⁴

Remove any excess material with the stick end of the cotton-tipped applicator. Use the discoid-cleoid dental carver to remove excess material once it begins to harden (**Figure 213-3B**). Use dental floss to contour a proper embrasure and clear excess material from the gingival tissues. **Use the dental floss in a downward direction only. Never bring the dental floss back up toward the occlusal surface because doing so risks dislodging the new restoration.** Simply pull the dental floss through after one downward pass around the tooth.

REPLACING A TEMPORARY OR PERMANENT CROWN

The patient preparation required for this procedure is essentially the same as that for replacing a temporary filling. However, avoid dental anesthesia if possible to allow better patient proprioception. This will provide the Emergency Physician with a crucial aid in assessing the orientation and occlusion of the final restoration.¹ The same

over-the-counter mixtures for repairing a filling may be used to temporarily replace a crown (**Figure 213-2**).

Reapply the crown to ensure that it fits properly. It is often necessary to remove a small amount of the existing cement from within the patient's existing restoration in order to provide an adequate seal and a proper occlusion.¹ This may or may not be possible to do with the discoid-cleoid dental carver. Do not use rotary instruments as these may irreversibly damage the inside of the coping. Reinsert the patient's crown after removing some of the cement to assure a proper fit and proper occlusion. Make an attempt using the alternative technique described below if sufficient preexisting cement cannot be removed and the crown seats properly. Treat dentin sensitivity as outlined above (i.e., as replacing a filling) if the appliance does not seat at all.

Proceed with this technique if the restoration appears to fit and a small amount of the preexisting cement can be removed from the inside. Prepare the area. Apply a thin layer of petrolatum-based lubricant (e.g., Vaseline) to the mucosal tissues surrounding the tooth to aid in the cleanup. **Do not contaminate the prepared tooth with the lubricant.**

Prepare or mix a thin consistency of zinc oxide and eugenol cement. Place a very small amount of the mixture into the preexisting crown with a cotton-tipped applicator.^{3,14,18} Place the crown on the tooth and in the proper orientation. Firmly and fully seat the crown with firm finger pressure. Remove any excess cement material from around the margin of the newly cemented restoration. This may be easier once the material has hardened. Instruct the patient to gently and fully occlude on the restoration. **Ensure proper occlusion.** Ask the patient to provide a subjective report as to whether their occlusion feels like baseline (i.e., does their bite feel funny or normal). Confirm this using articulating paper to ensure that the contact marks are light or minimal. Wipe the petrolatum-based lubricant from the mucosal tissues.

A simpler alternative and far more temporary method of replacing a crown involves using Vaseline as the cementing agent.¹ Apply a thin layer of Vaseline to the inside of the coping. It may be necessary to remove a small amount of the preexisting cement. Seat the crown on the tooth in the proper orientation. Ensure proper occlusion. Warn the patient that the crown may come off again and about the risk of aspiration. Instructions may be given to the patient for repeating the procedure at home.

FIGURE 213-3. Application of temporary restorative material. **A.** Pack the material into the defect and condense it with a dental explorer (or a cotton-tipped applicator). **B.** Remove any excess material.

Another simple approach for replacing a crown is to use cyanoacrylate. Similar to the Vaseline method, place a thin layer inside the coping and seat the crown on the tooth in the proper orientation. Have the patient gently and fully occlude on the restoration.²⁶

ASSESSMENT

Check the patient's occlusion. It may be necessary to use articulating paper to ensure minimal or no contact with the opposing teeth with the temporary filling. The newly cemented crown restoration must primarily be assessed for proper occlusion. The patient's subjective opinion is invaluable in this regard.

AFTERCARE

Instruct the patient not to eat or chew on their new restoration for at least 1 hour. Additional instructions should include a soft diet, avoidance of extremely hot or cold substances, avoidance of chewing gum, and avoidance of other such "sticky" foodstuffs. They may brush their teeth normally but should not floss adjacent to the new restoration. Warn them that they may experience some continued sensitivity. Nonsteroidal anti-inflammatory drugs will provide any needed analgesia. Arrange follow-up within 24 to 48 hours.

COMPLICATIONS

Typical complications of replacing a filling include improper occlusion and poor retention of the restoration. The solution for both problems is replacing the restoration. Adjust the occlusion with the discoid-cleoid dental carver. Treat the restoration as a dental restoration that is "too high" if using the discoid-cleoid dental carver is not effective. Treat the tooth as a simple dentin exposure if a temporary restoration is continually falling out. An unlikely complication would be pulp exposure manifested as minimal bleeding from within the tooth defect.^{1,10,12} Manage this as a dental trauma or fractured tooth (Chapter 215).

Typical complications for replacing a crown are similar to those listed in replacing a temporary filling. These restorations are often easily removed with a slight twisting motion. A restoration that is seated "too high" should be replaced. Treat the tooth as a simple dentin exposure if a restoration is consistently "too high."

SUMMARY

Management of the patient with a dental complaint may initially seem intimidating to the Emergency Physician. The recognition and treatment of dental pain, minor defective dental restorations, and painful mucosal conditions can be relatively simple provided the Emergency Physician possesses a minimal understanding of basic dentistry. Emergency Physicians must be cognizant of the inherent limitations involved in treating these patients in the Emergency Department. Have a low threshold for referral. Pain, inflammation, and infection should always be treated. Refer patients to the appropriate specialist within 24 to 48 hours.

Subluxed and Avulsed Tooth Management

Richard Dean Robinson, Adam Flink, and Ryan Nathaniel Krech

INTRODUCTION

Traumatic dental injuries are a common presentation to the Emergency Department.¹⁻⁶ They can have significant lasting cosmetic, functional, and psychological consequences for the patient. Recent estimates indicate over three quarters of a million annual Emergency Department visits in the United States occur for dental-related complaints.⁷ Nearly 12% of these are related to some form of trauma.⁷ Approximately 50% of children will sustain traumatic dental injuries, the majority of these to the permanent dentition.⁸⁻¹⁰ Violence of

a suspicious nature, such as domestic adult abuse and child abuse, must always be considered when evaluating dental injuries.

The appropriate Emergency Department management of dental trauma depends heavily upon the type of tooth (i.e., permanent versus primary), the age of the tooth, the time elapsed since the dental trauma, and the extent of the damage. Successful treatment of dental injuries requires a basic understanding of dental anatomy, terminology, and pathophysiology. **The goals of the emergent treatment of dental trauma are to maintain patient comfort and tooth viability while ensuring prompt dental follow-up for definitive care.**

ANATOMY AND PATHOPHYSIOLOGY

TOOTH ANATOMY

There are significant differences in the adult and pediatric dentition that impact their treatment in the Emergency Department (Figure 214-1). The pediatric dentition is known as the primary or deciduous dentition and consists of 20 teeth. These include 8 incisors, 4 canines, and 8 molars. The adult dentition consists of 32 teeth and is composed of 8 incisors, 4 canines, 8 premolars, and 12 molars. The variable absence of a tooth or the addition of an extra tooth is common in either dentition. Teeth in both pediatric and adult dentitions erupt in a predictable sequence, albeit with considerable individual variation (Figure 214-1). Treatment strategies differ for permanent versus deciduous (i.e., primary) teeth as well as by the age of the adult tooth. **Exercise great care when evaluating patients with a “mixed” dentition, roughly between the ages of 6 and 12 years.**

The anatomy of a tooth is rather simple (Figure 214-2). The tooth itself consists of a neurovascular pulp surrounded by supportive dentin which is surrounded by a hard thick crown of enamel. The

FIGURE 214-2. The dental anatomic unit (i.e., the tooth) and its supporting structures.

crown portion lies above the gum line or gingiva. The root portion lies embedded within the alveolar bone of the jaw anchored by a thin layer of cementum and the periodontal ligament. The alveolar bone, periodontal ligament fibers, and fragile cementum cell layer taken together are considered a functional unit known as the attachment apparatus. A complete attachment apparatus requires an intact cementum cellular layer and a fully formed root apex. Immature adult teeth do not have a fully formed apex and necessitate special attention to maintain pulp viability.^{9,11-15}

TOOTH INJURY

Mechanisms of tooth injury include direct trauma (i.e., a blow) or occlusive trauma (i.e., biting on a hard object or a seizure). These mechanisms can result in a spectrum of injury patterns that vary from simple sensitivity to complete tooth avulsion. Crown and root fractures are discussed in Chapter 215. This chapter focuses on the diagnosis and management of dental subluxations and avulsions.

Appropriate treatment of dental injuries requires a thorough history and meticulous examination of the oral cavity including subsequent radiographs after ruling out more serious injuries. Important points in the history include the age of the patient, the time of the trauma, the mechanism of injury, the location of teeth or tooth fragments, subjective disturbance of bite, and treatments provided since the time of the incident. The physical examination must include an assessment of the extraoral and intraoral soft tissues, bony displacement, missing teeth, crown fractures, pulp exposures, tooth sensitivity, and tooth mobility.

The need for radiographs with dental trauma is worth emphasizing. A tooth that is missing, both by history and physical examination, may be found completely intruded below the gum line, embedded in the periosteal soft tissues, floating within the maxillary sinus or stomach, or aspirated into the airway.¹⁶⁻²¹ **Obtain facial films if a tooth, or a portion of the tooth, cannot be unequivocally located by history or physical examination. Strongly consider obtaining chest and abdominal radiographs if the tooth, or the portion in question, is not visualized on the facial films.**

FIGURE 214-1. The normal eruptive patterns of the pediatric and adult dentition.

CONCUSSED AND SUBLUXED TEETH

Mild injuries to teeth are common and cause concussions and subluxations. Concussed teeth are essentially injured, not mobile, and not fractured teeth. These teeth have suffered a direct blow and are sensitive with no concrete clinical or radiographic evidence of injury. Concussions are often mild injuries to the periodontal ligament with associated inflammation. Subluxed teeth may or may not be sensitive, are not displaced, but are perceptively mobile when manipulated between two cotton applicators or other instruments. Subluxations have definite damage to the periodontal ligament with associated inflammation. Mild gingival bleeding may be present. **Both a concussion and a subluxation imply an injury to the attachment apparatus.** Pain control, soft diet instructions, and follow-up with a Dentist are all that is required in the management of most of these injuries. Concussed and subluxed primary and permanent teeth are generally treated in the same manner.^{8,13-15}

Excessive mobility from a severe subluxation may be irritating, painful, and damaging. These injuries require a temporary splint for relief.^{8,9,11-15} Definitive treatment for severely subluxed permanent teeth requires splinting for 2 weeks or more.¹⁵ Definitive treatment for severely subluxed primary teeth is extraction.¹⁵

LUXATED TEETH

Luxated teeth are displaced or dislocated from their usual position within the alveolar bone. The periodontal ligament is torn. Luxated teeth are commonly associated with other injuries such as alveolar fractures, root fractures, and gingival lacerations.^{8,22} Subcategories of injury within this class are described by the direction of the dislocation. Luxated teeth may be displaced laterally, intruded, or extruded (Figure 214-3). Lateral luxations may be mesial, distal, buccal, or lingual in direction. An alveolar fracture is self-evident when several teeth are luxated as a solid segment.

Laterally luxated permanent teeth should be repositioned and temporarily splinted.¹³⁻¹⁵ Laterally luxated primary teeth can be treated in the same fashion.¹⁵ A general word of caution regarding primary teeth is warranted. **The apices of the primary teeth are in close anatomic proximity to the developing permanent tooth buds within the alveolus. This close relationship can lead to numerous developmental disturbances in the permanent dentition whenever there is trauma to a primary tooth.**²³ Therefore, it is recommended that the Emergency Physician defer any

manipulation of a primary tooth to the care of a Dentist or at least consult them first.

Extruded teeth represent a partial avulsion from the alveolar socket and a damaged attachment apparatus. They typically appear clinically longer than the surrounding teeth (Figure 214-3B). Patients may complain of occlusal prematurity. There may be associated gingival bleeding. A hematoma surrounding the apex may preclude complete repositioning. Extruded permanent teeth are treated with repositioning and temporary splinting.^{8,9,11,13-15} Treatment decisions for extruded primary teeth are complex and best left to a Dentist. The majority of these teeth will likely require extraction.¹⁵

Intrusion is a severe form of luxation injury with the tooth driven inward in an axial direction. These injuries are manifested by displacement of the tooth into the alveolar socket with a corresponding fracture of the alveolar bone surrounding the apex (Figure 214-3A). Adjacent structures, such as the floor of the nose or maxillary sinus, may be involved or damaged.^{19,20} These injuries may be so profound that the tooth is not visible within the oral cavity and believed to be avulsed. **It is worth reiterating that a tooth that cannot be unequivocally located on physical examination requires radiographic localization.** Immature adult teeth suffering intrusion injuries generally have the best prognosis. They are often left alone and allowed to re-erupt. Mature adult teeth often require surgical or orthodontic assisted re-eruption and root canal therapy. The intrusion of primary teeth frequently leads to damage of the developing permanent tooth buds and requires close dental follow-up. Rule out more serious injuries, arrange an expedited appointment for definitive care, prescribe appropriate analgesics, and give strong consideration to the prescription of antibiotics.^{8,9,11,13-15,24}

AVULSED TEETH

Avulsed teeth are teeth that have been completely torn from their alveolar sockets. **The teeth have suffered profound attachment and neurovascular damage that progresses in a time-dependent fashion.** There is a high likelihood of associated injuries with this type of trauma. Perform a thorough evaluation of the entire oral cavity after any dried blood, clots, and debris have been removed. Bleeding can generally be controlled with firm digital pressure or local infiltration of an epinephrine-containing local anesthetic solution. Patients may present with the tooth in hand or may not be aware of the location of the tooth. **The onus is on the Emergency Physician to determine the exact whereabouts of the tooth. Treat the patient's pain, control the bleeding, and provide tetanus prophylaxis.** Prescribe antibiotics for these patients if there are significant concomitant injuries or as the situation warrants. Arrange follow-up with a Dentist at their convenience. If available, a permanent tooth can be treated with replantation. **As a rule, avulsed primary teeth are not replanted to avoid damage to the developing permanent teeth and possible growth disturbances.**^{11,13-15} Exercise great care in evaluating patients in the mixed dentition stage roughly between the ages of 6 and 12 years.^{8,9,11}

An attempt can be made at replantation in order to preserve patient comfort, cosmesis, and function when a permanent avulsed tooth is available. **The objective for the emergency treatment of these injuries is to maintain viability of the torn periodontal ligament fibers on the external root surface as pulp necrosis is inevitable for the majority of these teeth.**⁸ A successfully replanted tooth may be fully functional with little or no cosmetic impact following root canal therapy. **Periodontal ligament fibers are extremely sensitive to desiccation. The most critical factor in the successful replantation of avulsed teeth is the speed with which the tooth is replanted.**^{8,9,22,25} Patients, parents, or Emergency Medical Service personnel can be instructed to replant an avulsed tooth in the field in order to improve the prognosis.^{8,9}

FIGURE 214-3. Luxation injuries with neurovascular damage to the apex. **A.** Intrusive luxation injury. **B.** Extrusive luxation injury.

Take great care in the handling of an avulsed tooth. They should be handled minimally and only by the crown. The root surface should not be manipulated in any way other than gentle cleansing with sterile saline or tap water as a substitute. This will prevent further damage to the cementum and periodontal ligament. Treat the socket in a similar fashion (i.e., cleansed of any obstructing clots or debris with gentle irrigation and suction only) following anesthesia.^{9,25}

When it is not possible to immediately replant an avulsed tooth, it can be transported or stored in such a way as to prevent desiccation of the fragile periodontal ligament fibers and to improve salvage rates.^{8,11,13-15} The best possible transport and storage solutions are Hank's balanced salt solution (HBSS) and Viaspan, a special cell culture medium (SCCM) used to preserve transplant tissues. The SCCM seems to show some benefit over HBSS.²⁶ Several commercial products are readily available and specifically designed for tooth transportation and storage. They include EMT Tooth Saver (SmartPractice, Phoenix, AZ) and Dentosafe (Medice, Iserlohn, Germany) which utilize SCCM or Save-a-Tooth (Phoenix-Lazerus, Pottstown, PA) which utilizes HBSS.²⁶ These products have great utility in the field and the Emergency Department. They should be considered standard and essential equipment for the Emergency Department. This is particularly true where definitive dental care is not readily available. Simply providing a patient with one of these products may allow successful replantation by a dental specialist hours or even days later.^{8,27} Fresh pasteurized whole milk and sterile normal saline are alternatives but carry diminishing returns for salvaging the tooth. Saliva can be employed as a transport medium by placing the tooth in the buccal vestibule of a conscious and cooperative adult for very brief periods, again with diminishing hopes for salvage. Tap water or plastic wrap may prevent desiccation for a brief period if all else fails.^{9,11,13-15,27}

The literature indicates that irreversible periodontal ligament cell damage occurs within minutes following total tooth avulsion.^{9,11,25} Common clinical practice is typically to abandon attempts at salvaging the tooth if it has been out of the socket for more than an hour. **However, the notion that replantation is not possible for extraoral times beyond 1 hour is a myth.** The dental trauma literature is replete with case reports of successful outcomes following very long extraoral times (e.g., up to a week) and under extremely suboptimal storage conditions such as being kept completely dry.^{27,28} An aesthetic and functional, albeit less than ideal, result may be possible for avulsed teeth with extraoral times over an hour through a process known as ankylosis if appropriately and aggressively treated by a skilled Dentist. **Therefore, it is never acceptable to discard an avulsed tooth.** Avulsed teeth with extraoral times greater than 1 hour require special treatment with topical fluoride and antibiotic soaks that are typically beyond the scope of care in the Emergency Department.^{15,25} Consult a Dentist prior to considering these techniques. At the very least, always give the patient their tooth back in a suitable storage or transport device and advise them on their options for definitive care.

REDUCTION OF SEVERELY SUBLUXED, LATERALLY LUXATED, AND EXTRUDED TEETH

The emergent treatment of a severely subluxed tooth, a laterally luxated tooth, or an extruded tooth involves obtaining adequate anesthesia, reduction of the tooth, and a temporary splint for stabilization.

INDICATIONS

Any severely subluxed, laterally luxated, or extruded tooth is a candidate for reduction.

CONTRAINDICATIONS

There are no absolute contraindications to the reduction of a subluxed, laterally luxated, or extruded permanent tooth. Laterally luxated and primary teeth can be repositioned and splinted. However, their manipulation may damage the permanent tooth bud growing beneath the primary tooth root. Therefore, all subluxed, luxated, or extruded primary teeth should be considered for extraction in consultation with a Dentist or Oral Surgeon.^{11,13-15,22,29} Consult a Dentist or Oral Surgeon if there is a significant alveolar bone fracture. Do not attempt to reduce teeth that are fractured or grossly carious.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 or 27 gauge needle
- Sterile saline
- Sterile 2×2 gauze squares
- Suction source and tubing
- Frazier suction catheter
- Cotton-tipped applicators
- Overhead lighting or headlight

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia (Chapter 209). Cleanse the oral cavity with warm saline or tap water and gentle suction. Thoroughly examine the entire oral cavity. Obtain radiographs as indicated. Provide tetanus prophylaxis if required.

TECHNIQUES

SEVERELY SUBLUXED TOOTH REDUCTION

A severely subluxed tooth is not displaced from its socket but is excessively mobile. Ensure that the tooth is in its proper anatomic location. Apply a temporary dental splint as described below.

LATERALLY LUXATED TOOTH REDUCTION

A laterally luxated tooth has its roots displaced laterally and out of the socket (**Figure 214-4**). It is often associated with a fracture of the surrounding alveolar bone. Place the dominant thumb over the medial surface of the tooth and the index finger overlying the root end of the tooth (**Figure 214-4**). Apply downward and inward pressure with the index finger (**Figure 214-4A**) followed by application of outward pressure with the thumb (**Figure 214-4B**) to reduce the tooth. Apply a temporary dental splint as described below.

EXTRUDED TOOTH REDUCTION

An extruded tooth is a partially avulsed tooth that protrudes above the adjacent teeth. Apply gentle pressure to the crown of the tooth to reduce the tooth. **Do not force the tooth into the socket to avoid an iatrogenic fracture at its base.** Consult a Dentist if the tooth will not reduce. A hematoma in the base of the socket often prevents reduction. Insert a piece of gauze over the tooth and instruct the patient to gently bite down.

FIGURE 214-4. Manually repositioning a laterally luxated tooth. Apply downward and inward pressure with index finger (A) followed by outward pressure with the thumb (B).

ASSESSMENT

Obtain postreduction radiographs to verify the correct tooth position. Radiographs may be delayed until after splinting. Reassess the patient for pain, occlusal discrepancies, and stability of the reduction. Manage any soft tissue injuries.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesics will provide adequate analgesia. Prescribe empiric antibiotics (e.g., penicillin or clindamycin). Twice daily rinses with chlorhexidine may also be useful. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care as discussed below. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.^{8,9,24}

COMPLICATIONS

Immediate complications of any dental trauma include pain and cosmetic deformity. Additionally, instability may be an issue following the application of a temporary splint. Delayed complications can be variable and include tooth mobility, root resorption, pulp necrosis, infection, and abscess formation. Extension of untreated infections into alveolar bones can cause osteomyelitis and/or systemic infectious complications. A permanent tooth may develop abnormally in a younger child if injured. Bleeding is minimal and often self-limited. Refer to Chapter 212 for details of post-extraction bleeding management. Ensuring prompt dental follow-up, adequate outpatient analgesics, and empiric antibiotics can limit most of these complications.

REPLANTATION OF AN AVULSED TOOTH

Permanent teeth that have been avulsed should be handled gently and only by the crown. Time is a critical factor in the successful treatment of these injuries and every effort should be made to expedite the care of these patients. Replantation consists of gently

reinserting the tooth in the proper orientation and fully seating it with gentle pressure.

INDICATIONS

Any intact and avulsed permanent tooth is a candidate for replantation.³⁰⁻³²

CONTRAINDICATIONS

There are no absolute contraindications to the replanting of permanent teeth by nondental personnel. Concerns for the ABCs (airway, breathing, and circulation), concomitant major morbidity, and aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth replantation. Primary teeth are never replanted. Do not attempt to replant teeth that are fractured or grossly carious.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 or 27 gauge needle
- Sterile saline
- Hank's balanced salt solution
- Sterile 2×2 gauze squares
- Sterile cotton rolls
- Suction source and tubing
- Frazier suction catheter
- Cotton-tipped applicators
- Overhead lighting or headlight

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia (Chapter 209). Cleanse the oral cavity with warm saline or tap water. **Use gentle suction but never near the injured tooth.** Thoroughly examine the entire oral cavity. Obtain radiographs as indicated. Provide tetanus prophylaxis and antibiotics if required. Gently irrigate the avulsed tooth and socket with warm sterile saline or Hank's solution. Remove any clots and debris using a Frazier suction catheter. **Take great care to avoid touching or contaminating the tooth root.** Soak the tooth in Hank's solution for 30 minutes prior to replantation if the extraoral dry time exceeds 30 minutes. Consult a Dentist skilled in dental trauma care prior to replanting if the extraoral time exceeds 1 hour.

If the apex of the tooth is open, consider soaking the tooth for 5 minutes prior to replantation in a solution of 1 mg of doxycycline in 20 mL of normal saline which may improve pulp revascularization. The soaking of avulsed monkey teeth in doxycycline for 5 minutes prior to reimplantation showed improvement in revascularization of the pulp and root development.³³ However, a more recent study showed no increased benefit in pulp survival with soaking the tooth in doxycycline compared to saline.³⁴

TECHNIQUE

Grasp the avulsed tooth gently and only by the crown. Replace the avulsed tooth into the socket in an anatomically correct position. Seat the tooth fully with gentle but firm digital pressure. **Never force the tooth into the socket.** Evaluate the patient's occlusion. Instruct the

patient to gently bite together several times while observing for any prematurity. Occasionally, a tooth cannot be completely seated or its position is uncertain. Instruct the patient to temporarily bite on a gauze roll until the dental specialist arrives or store the tooth in a storage or transport medium until definitive dental care can be rendered.^{9,24} Address any soft tissue injuries once the tooth's position has been verified. Insert a piece of gauze over the tooth and instruct the patient to gently bite down. Apply a temporary dental splint as described below.

ASSESSMENT

Obtain postreplantation radiographs to verify the correct tooth position. Radiographs may be delayed until after splinting. Reassess the patient for pain, occlusal discrepancies, and stability of the replanted tooth prior to discharge. Manage any soft tissue injuries.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesics will provide adequate analgesia. Prescribe empiric antibiotics. Doxycycline is recommended as the drug of choice in patients over 12 years of age. Penicillin and clindamycin are useful substitutes. Twice daily rinses with chlorhexidine are useful but not required. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care as discussed below. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.^{8,9,24}

COMPLICATIONS

Immediate complications of any dental trauma include pain and cosmetic deformity. Additionally, instability may be an issue following the application of a temporary splint. Delayed complications can be variable and include tooth mobility, root resorption, pulp necrosis, infection, and abscess formation. Extension of untreated infections into alveolar bones can cause osteomyelitis and/or systemic infectious complications. A permanent tooth may develop abnormally in a younger child if injured. Bleeding is minimal and often self-limited. Refer to Chapter 212 for the details of post-extraction bleeding management. Ensuring prompt dental follow-up, adequate outpatient analgesics, and empiric antibiotics can limit most of these complications.

PREPARING A TEMPORARY DENTAL SPLINT

Concussed teeth, subluxed primary teeth, and subluxed permanent teeth usually do not require splinting. A temporary splint may prevent further damage and improve patient comfort if severe mobility or subluxation is present. Manually reposition laterally luxated and extruded permanent teeth using gentle and firm digital manipulation following adequate anesthesia. A Dentist or Oral Surgeon will typically extract laterally luxated or extruded primary teeth. Intruded teeth, both primary and adult, are associated with considerable comorbidity and complications. These injuries require consultation with a Dentist or Oral Surgeon after defining the extent of the injuries with appropriate radiographs.

INDICATIONS

Any severely traumatized and grossly mobile, luxated, repositioned, or replanted tooth requires temporary splinting. This will prevent further damage, promote patient comfort, preserve form, and preserve function.

CONTRAINDICATIONS

There are no absolute contraindications to the temporary splinting of mobile teeth. The aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth splinting.

GENERAL SPLINTING EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe or a 3 mL syringe with a 2 inch, 25 or 27 gauge needle
- Sterile saline
- Coe-Pak or Perio-Pak
- Dental utility wax or beeswax
- Sterile 2×2 gauze squares
- Sterile cotton rolls
- Applicator sticks; tongue depressors or the wooden end of cotton swabs will substitute
- Frazier suction catheter
- Suction source and tubing
- Overhead lighting or headlight

ADVANCED SPLINTING EQUIPMENT

- General splinting equipment as described above
- Wire cutters
- Tooth etching gel
- Composite resin material (e.g., Centrix Tempit Ultra-F, Centrix Inc., Shelton, CT)
- Single-component adhesive (e.g., Optibond Solo Plus Kit, Kerr Corp., Orange, CA)
- Bondable reinforcement ribbon (e.g., Ribbond, Ribbond Inc., Seattle, WA)
- Orthodontic wire, 0.025 inch
- Tubing and regulator to attach to wall air supply
- Visible curing light

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient in a multipositional procedure chair with good overhead lighting. Administer dental anesthesia, cleanse and thoroughly examine the entire oral cavity, obtain radiographs as indicated, and provide tetanus prophylaxis and antibiotics if required if not done earlier. Manually reposition any luxated and avulsed teeth. **Manage any soft tissue injuries prior to splint placement to avoid wound contamination by the splint material.**

TECHNIQUES

Cold-curing periodontal packing material (i.e., Coe-Pak or Perio-Pak) is an ideal splinting material for practitioners without dental experience. Measure out equal amounts (i.e., lengths) of the catalyst and the epoxy onto a paper pad (**Figure 214-5A**). A 2 to 3 inch long ribbon of each substance is usually adequate. Thoroughly mix the catalyst and epoxy compounds together with a tongue depressor to form a putty-like consistency (**Figure 214-5B**). Using tap water- or saline-wetted gloved hands, roll the material into a log (**Figure 214-5C**). Apply the material to frame both aspects, medial

FIGURE 214-5. Preparation of the dental bonding resin and repair of the injured tooth. **A.** Equal amounts of the epoxy and catalyst are measured. **B.** The epoxy and catalyst are mixed together. **C.** The hardening dental paste is molded into a supportive bridge. **D.** The dental bridge is applied over the injured tooth and adjacent two uninjured teeth (both sides) for support while hardening.

and lateral, of the injured tooth and two to three adjacent stable teeth on either side of the injured tooth (**Figure 214-5D**). Use finger pressure to squeeze the material between the teeth medially and laterally to create a single splint unit. **To allow proper occlusion, do not place the packing material on the masticatory surfaces of the teeth. The material must be kept dry and uncontaminated to cure which is achieved within minutes.**

ALTERNATIVE TECHNIQUES

Numerous alternative techniques have also been used to temporarily splint a tooth. A simpler technique employs softened dental utility wax or beeswax in a similar fashion as described above. The wax splint is not nearly as stable as the cold-curing periodontal packing. Both the medial and lateral surfaces of the teeth can be splinted in this fashion. Ligature splinting with suture material has been described but rarely provides any significant stability.

Advanced techniques include bondable reinforcement ribbon, acid-etched composite resin, direct interdental wiring, resin-wire combinations, arch bars, and stabilization with a figure-of-eight stitch to the adjacent tooth.³⁵⁻³⁷ These are excellent materials in experienced hands. Unfortunately, they are difficult to use, fraught with complications, and cost prohibitive for routine Emergency Department use.^{8,9,11,12,21,22,24,29} Two of these methods, which can be performed by the Emergency Physician if supplies are available, are described below. In an emergency with no immediate dental supplies or available Dentist, skin wound glue (2-octyl cyanoacrylate) and a metal nasal bridge from a face mask have been used to splint a tooth.³⁸

Teeth may be splinted using bondable reinforcement ribbon. Open the Ribbond kit. Use the included scissors to cut a piece of the splinting fabric long enough to span the length of the injured tooth and one tooth on each side of the injured tooth. Apply a small drop of the acid etching solution onto all three teeth (i.e., the

injured tooth, the one behind it, and the one in front of it). Allow the acid etching solution to remain on the teeth for 20 seconds. Thoroughly and gently rinse the acid etching solution using warm tap water or warm sterile saline in a syringe while using suction to capture the liquid. It is often easier to etch and rinse one tooth at a time instead of all three simultaneously. Thoroughly dry the teeth with compressed air. Remove the Optibond Solo Plus container from its packaging. Twist and remove the tip from the Optibond Solo Plus container. Apply a layer of the Optibond Solo Plus to the etched surface of all three teeth using the kit's micro brush. Apply the curing light to the three teeth for 20 seconds each. Apply Optibond Solo Plus onto the previously cut splinting fabric until it is saturated. Apply the tip onto the syringe containing the composite resin. Apply the composite resin to each of the three teeth. Apply and embed the splinting fabric into the composite resin on each tooth. Use a wooden stick (e.g., tongue depressor or cotton-tipped applicator) to ensure the fabric is embedded in the resin as well as covered by the resin. Apply the curing light onto the three teeth for 40 seconds each. The procedure is the same if multiple adjacent teeth require splinting.

A tooth may be splinted using wire and composite resin. Use a wire cutter to cut a piece of orthodontic wire long enough to span the length of the injured tooth and one tooth on each side of the injured tooth. The remainder of the procedure is exactly as described above except the orthodontic wire is substituted for the splinting fabric.

ASSESSMENT

Allow the patient to wait in the Emergency Department until the splinting material has hardened. The splint material should impinge minimally on the soft tissues. The patient must be able to open and close their mouth and lips freely without any obstruction. Reassess the patient for pain, occlusal discrepancies, and stability of the

replanted or subluxed tooth prior to discharge. Obtain postsplinting radiographs to verify the proper tooth position.

AFTERCARE

Prescribe appropriate analgesics. Nonsteroidal anti-inflammatory drugs supplemented with occasional narcotic analgesics will provide adequate analgesia. Prescribe empiric antibiotics. Instruct the patient to avoid extremely hot or cold substances, to eat a liquid or soft diet, and to avoid chewing in the area of the injury. Provide specific instructions regarding interim dental splint care. Arrange follow-up with a Dentist or Oral Surgeon within 24 hours. Remind the patient that any dental injury can result in the loss of tooth vitality and, ultimately, the loss of the tooth despite the best of efforts to maintain it.^{8,9,24}

COMPLICATIONS

The complications of temporary dental splinting are minimal. The splint material may not stabilize the tooth. A tooth allowed to move within the socket may result in damage to the cementum or the periodontal ligament. An improperly splinted tooth may fall out and result in an aspiration risk. To prevent irritation and bleeding, do not apply splinting materials over the soft tissues. Do not leave the etching acid on longer than 20 seconds or it can penetrate too deep and damage the tooth.

SUMMARY

Traumatic dental injuries are a common presentation to the Emergency Department, especially in pediatric patients during the mixed dentition stage. These injuries may have significant cosmetic, functional, and psychological consequences for the rest of the patient's life. The appropriate Emergency Department management of dental trauma depends heavily upon the type of tooth involved (i.e., primary versus permanent), the time elapsed since the incident, and the extent of the damage. A basic understanding of dental anatomy, terminology, pathophysiology, and treatment protocols will facilitate an accurate description of the extent of the injuries to the dental consultant and be of great aid in providing temporizing emergent dental care when no specialist is readily available. In the future, a subluxed or avulsed tooth may be easily replaced with a 3D-printed tooth made of antimicrobial plastic.³⁹

Fractured Tooth Management

Richard Dean Robinson, Mahmuda Farha, and Bharti Chaudhari

INTRODUCTION

Traumatic dental injuries are common and can have significant lasting consequences for the patient. Recent estimates indicate over three quarters of a million annual Emergency Department visits in the United States for dental-related complaints.¹ Nearly 12% of these are related to some form of trauma.¹ It has been estimated that approximately 50% of children will sustain traumatic dental injuries, and the majority of these are to permanent dentition.²⁻⁴ **Violence of a suspicious nature such as domestic adult abuse, child abuse, and child neglect must always be considered when evaluating dental injuries. The goals of the emergent treatment of dental trauma are to maintain patient comfort and tooth viability while ensuring prompt dental follow-up for definitive care.**

ANATOMY AND PATHOPHYSIOLOGY

TOOTH ANATOMY

There are significant differences in adult and pediatric dentition that impact their treatment in the Emergency Department (Figure 215-1). The pediatric dentition is known as the primary or deciduous dentition and consists of 20 teeth, which includes 8 incisors, 4 canines, and 8 molars. The adult dentition consists of

FIGURE 215-1. The normal eruptive patterns of the pediatric and adult dentition.

FIGURE 215-2. The dental anatomic unit (i.e., the tooth) and its supporting structures.

32 teeth and is composed of 8 incisors, 4 canines, 8 premolars, and 12 molars. The variable absence of a tooth or the addition of an extra tooth is common in either dentition. The teeth in both the pediatric and adult dentitions erupt in a predictable sequence, albeit with considerable individual variation (Figure 215-1). Treatment strategies differ for permanent versus deciduous (i.e., primary) teeth as well as by the age of the adult tooth.⁵⁻⁸ **Exercise great care when evaluating patients with a “mixed” dentition, roughly between the ages of 6 and 12 years.**

The anatomy of a tooth is rather simple (Figure 215-2). The tooth itself consists of a neurovascular pulp surrounded by supportive dentin which is surrounded by a hard thick crown of enamel. The crown portion lies above the gum line or gingiva. The root portion lies embedded within the alveolar bone of the jaw anchored by a thin layer of cementum and the periodontal ligament. The alveolar bone, periodontal ligament fibers, and fragile cementum cell layer taken together are considered a functional unit known as the attachment apparatus. A complete attachment apparatus requires a fully formed root apex. Immature adult teeth do not have a fully formed apex and necessitate special attention to maintain pulp viability.^{2-4,9}

TOOTH INJURY

Mechanisms of tooth injury include direct trauma (e.g., a blow) or occlusive trauma (e.g., biting on a hard object or a seizure). These mechanisms can result in a spectrum of injury patterns that vary from simple sensitivity to complete tooth avulsion. The fracture of any portion of the tooth, whether the crown or the root, falls in the middle of this spectrum and is frequently seen in the Emergency Department.⁴

Appropriate treatment of dental injuries requires a thorough history and meticulous examination of the oral cavity including subsequent radiographs after ruling out more serious injuries. Important points in the history include the age of the patient, the time of the trauma, the mechanism of injury, teeth or tooth pieces at the scene, subjective disturbance of bite, and the treatments provided since the time of the incident. The physical examination must include an assessment of the extraoral and intraoral soft tissues, bony

displacement, missing teeth, crown fractures, pulp exposures, tooth sensitivity, and tooth mobility. This chapter focuses primarily on tooth fractures while luxation and avulsion injuries are dealt with in Chapter 214.

The need for radiographs with dental trauma is worth emphasizing. A tooth that is missing, both by history and physical examination, may be found completely intruded below the gum line, impacted within the perioral soft tissues, floating within the maxillary sinus or stomach, or even aspirated. **Obtain facial films if a tooth, or a portion of a tooth, cannot be unequivocally located by history or physical examination. Strongly consider obtaining chest and abdominal radiographs if the tooth, or portion in question, is not visualized on the facial films.**¹⁰⁻¹⁵ Any available tooth fragments whether retrieved from the scene, the patient's perioral soft tissues, or the patient's pocket should be saved and stored for potential use during the definitive care process by the Dentist.^{13,16-18} Bonding techniques in the Emergency Department are not prudent due to multiple potential complications including bond failure and tooth fragment aspiration.

TOOTH FRACTURES

Fractures involving the crown of the tooth are commonly described in the emergency literature using the Ellis classification system (Figure 215-3).^{2,4,9,10,19,20} **An Ellis I fracture involves only the enamel portion of the tooth (Figures 215-3 and 215-4A).** These injuries typically are not sensitive or painful. They can result in a sharp edge of enamel that may irritate the tongue and other adjacent soft tissues. Emergency treatment may be as simple as smoothing the rough edge with an emery board or similar instrument.^{2,4,18,21} These injuries frequently involve the prominent anterior teeth and may be cosmetically unappealing. Reassure patients with these concerns that aesthetic restorations are possible by their Dentist.^{4,9,10,19,22} **Forewarn patients with even minor trauma and sensitivity that unseen or undiagnosed trauma at the apex of any traumatized tooth, even with an appropriately treated crown fracture, can compromise blood flow to the pulp and obviate the need for root**

FIGURE 215-3. The Ellis classification scheme of dental fractures through the crown.

Steiner, DDS. Part C: Photo contributor: Kevin J. Knoop, MD, MS.)

canal therapy.^{4,22} **Both primary and permanent teeth with these fractures can be treated in a similar fashion.**¹⁸

An Ellis II fracture involves the dentin (Figures 215-3 and 215-4B). It can be recognized by the yellow to pink hue of the dentin in contrast to the white of enamel. This fracture allows for potential contamination of the dentin microtubular network by oral bacteria that may eventually compromise the pulp if not treated. Dentin is alive, formed by the pulp, sensitive to temperature, sensitive to osmotic gradients, and sensitive to mechanical forces. Dentin is laid down concentrically from within the pulp chamber as the tooth ages. Therefore, children have less dentin than pulp (as compared to adults) and their pulp is less insulated against trauma and subsequent infection. Children under the age of 12 years with Ellis II fractures have a higher risk of complications and require more expeditious follow-up.^{2,9,18,22} **Refer these patients to a General or Pediatric Dentist as soon as possible.**

Emergency treatment for Ellis II fractures consists of applying a protective dressing that is also sedative to the pulp. Examples include Dycal (L.D. Caulk Co., Milford, DE) and IRM (L.D. Caulk Co.,

Milford, DE). These materials need to cover the entire exposed dentin (and therefore the dentin microtubules) in order to protect the pulp from contamination. These materials are then often covered with a sealant such as Copalite (Cooley & Cooley, Houston, TX), clear acrylic nail polish, or a dental bonding resin.^{2,3,9,10,18,19,22,23} Some authors have suggested that a non-light cured glass ionomer cement replace the long-held standard of Dycal.³ While these materials may offer some advantages, they can be expensive and difficult to use.²²

Tissue adhesives such as Dermabond (Ethicon, Inc., Somerville, NJ) have been suggested as alternative dressings in the treatment of Ellis II fractures.²⁴⁻²⁶ This should be discouraged as its effects on pulp tissues via exposed dentin microtubules have not been studied and are unknown. Physicians may actually be causing harm by using this material on exposed dentin.

Both primary and permanent teeth with Ellis II fractures can be treated in a similar fashion. However, like immature permanent teeth, primary teeth with Ellis II fractures require special care and more expeditious follow-up.¹⁸

An Ellis III fracture involves exposure of both the dentin and the pulp (Figures 215-3 and 215-4C). This is identified as a red-dish tinge or subtle bleeding from the exposed dentin. Frank pulp exposures are obvious. The pulp is highly vascular and exquisitely sensitive due to exposed nerve endings. The pulp is exceedingly vulnerable to bacterial infection if exposed. **These fractures constitute a true dental emergency and should be evaluated immediately by a Dentist or Oral Surgeon for possible emergent root canal therapy or extraction.** Although less than ideal, minimal pulp exposures (i.e., those less than 1 to 2 mm) may be treated as Ellis II fractures with dental follow-up within 24 hours.^{2-4,9,10,18,19,22} Complete coverage of the fractured crown may be difficult in these cases. Dental dry foil or tin foil may provide adequate coverage. Any root canal manipulation is fraught with complications, even in the hands of Endodontists. Emergency Physicians are well advised to avoid these procedures.^{2,19,22}

The pulp may be tricky to see in some cases of tooth fracture. A slight hint of pink may be seen under the dentin. **If pink is seen, do not explore deeper as you may open a thin layer of dentin covering the pulp.** Exploration may turn an Ellis II into an Ellis III fracture.

Fractures of the root are much less common than crown fractures and occur in less than 7% of dental injuries.^{2,4} Root fractures are uncommon in primary teeth as they have short roots.² Root fractures may be described as either horizontal or vertical. Horizontal root fractures are described according to their location along the tooth root (Figure 215-5). Vertical root fractures occasionally extend into the crown. All root fractures are prone to infection, impaired healing, and may ultimately lead to pulp necrosis and tooth loss.

The clinical diagnosis of root fractures is challenging at best, even with the aid of radiographs readily available in the Emergency Department (i.e., a Panorex). Root fractures classically present with pain, mobility, and sometimes displacement of a tooth fragment. However, these fractures are often insidious and found only on dental radiographs after follow-up reveals continued sensitivity. **Emergency Physicians must maintain a high level of clinical suspicion for these injuries and should probably err on the side of cautious overtreatment.**^{2,4}

Vertical root fractures and root fractures in the coronal portion of the root have a poor prognosis. Horizontal root fractures elsewhere along the tooth root have a good prognosis if treated within 24 to 72 hours before a coagulum can develop between the fragments.^{2,19} Immediate reduction and immobilization with one of the various splinting techniques is the treatment of choice. Refer to Chapter 214 for details regarding dental splinting techniques. Root fractures in primary teeth require extraction.¹⁸

FIGURE 215-5. Classification of root fractures according to their location. **A.** Incisal or coronal third fracture. **B.** Mid-root fracture. **C.** Apical third fracture.

INDICATIONS

Fractured teeth may require no treatment or a significant amount of treatment based upon the type of injury as described by the Ellis classification system. Fractured roots must be treated based upon the level of clinical suspicion.

CONTRAINDICATIONS

There are no absolute contraindications to the temporary repair of a fractured tooth or tooth root. Concerns for the ABCs (airway, breathing, and circulation), concomitant major morbidity, and aspiration risk in acutely or chronically debilitated patients should be considered prior to tooth repair.

EQUIPMENT

- Local anesthetic solution, with and without epinephrine
- Dental aspirating syringe, or a 3 mL syringe with a 2 inch, 25 or 27 gauge needle
- Dental explorer
- Discoid-cleoid carver
- Dental drill or emery board
- Sterile saline
- Sterile 2×2 gauze squares
- Sterile cotton rolls
- Applicator or molding sticks; tongue depressor or the wooden end of cotton swabs will substitute
- Calcium hydroxide paste (e.g., Dycal), mixable or premixed (preferred)
- Copalite cavity varnish or clear acrylic nail polish
- Zinc oxide eugenol paste (e.g., ZOE or IRM)
- Dental dry foil or tin foil

- Frazier tip suction catheter
- Suction source and tubing
- Good overhead lighting or headlight
- Dental floss

PATIENT PREPARATION

Explain the risks, benefits, and aftercare to the patient and/or their representative. Obtain an informed consent for the procedure. Position the patient upright in a multipositional procedure chair in a well-lighted environment. Provide tetanus prophylaxis as required. Provide anesthesia to the patient. Refer to Chapter 209 for the complete details regarding dental anesthesia and analgesia.

Irrigate the oral cavity and dental repair region with warm saline to remove any gross contaminants or clotted blood. Warm gentle irrigation is usually less sensitive to exposed dentin.¹⁹ **A dry and uncontaminated field is mandatory.** This can be achieved via dabbing with sterile cotton pellets or gently blowing with compressed air. Maintain a dry working environment by isolating the traumatized tooth with sterile cotton rolls on either side. Inject a small amount of local anesthetic solution containing epinephrine directly into the pulp if continued bleeding from a large pulp exposure is problematic.

A nasal cannula was successfully used as an alternative by some to keep an area dry that was constantly oozing blood. Aim the nasal cannula at a flow rate of 10 to 15 L of air or oxygen at the site prior to and during the procedure to keep the area dry. If the flow interferes with the procedure, intermittently use the nasal cannula to dry the area.

TECHNIQUES

ELLIS I FRACTURES

Ellis I fractures are clinically minor injuries (**Figures 215-3 and 215-4A**). Management includes smoothing of any sharp edges with a dental drill or a nail file to prevent injury or irritation to the soft tissues of the oral cavity. **Use care to avoid overly aggressive smoothing and exposure of the dentin (i.e., iatrogenic Ellis II injury).**

ELLIS II FRACTURES

Ellis II fractures are clinically more important than Ellis I fractures (**Figures 215-3 and 215-4B**). They require coverage of the exposed dentin to prevent infection and reduce sensitivity. Paint small or large dentin exposures with calcium hydroxide paste covering all of the exposed dentin.^{10,19,21} Apply the premixed calcium hydroxide paste in a thin layer with any small blunt instrument or the wooden handle of a cotton-tipped applicator. If not premixed, apply equal amounts of the calcium hydroxide base and catalyst on a piece of paper. Mix these two components thoroughly with a blunt instrument or wooden stick and then apply it to the tooth. **Allow the calcium hydroxide paste to completely dry.** Apply three to four coats of cavity varnish or clear acrylic nail polish over the dry calcium hydroxide paste. **Allow adequate drying time between the coats.** This will relieve any sensitivity. As an alternative to the cavity varnish or clear nail polish, place a tin foil dressing over the tooth to act as a bandage following placement of the calcium hydroxide paste.^{10,19,20} With cautious care, a calcium hydroxide dressing will typically last 2 to 3 days.²²

ELLIS III FRACTURES

Ellis III fractures are true dental emergencies and should be treated by a Dentist or Oral Surgeon (**Figures 215-3 and 215-4C**). Treat pulp exposures, if no specialist is immediately available, by

applying a saline-moistened or lidocaine-moistened cotton pledget over the exposed pulp and holding it there until the bleeding stops. This may take 2 to 5 minutes. Apply a thick mixture of calcium hydroxide paste over the exposed pulp and dentin. Apply the calcium hydroxide paste over an adjacent tooth also to form a temporary hold. Contour the calcium hydroxide paste so that it does not irritate the surrounding tissues. The majority of these injuries will require root canal therapy. Refer the patient to a Dentist within 24 hours if they are not seen by a specialist in the Emergency Department.

ASSESSMENT

Reassess the patient for pain and any occlusal discrepancies prior to discharge.

AFTERCARE

Most of these patients will have some degree of sensitivity until definitive treatment by a Dentist or Oral Surgeon. Prescribe appropriate outpatient analgesics. Nonsteroidal anti-inflammatory drugs supplemented with a narcotic analgesic will provide adequate pain control for Ellis II and III fractures. Antibiotics are generally not necessary unless the initial presentation had been significantly delayed, suppuration is present, or a significant delay is expected in obtaining dental follow-up. Instruct the patient to avoid extremely hot or cold substances, to begin a liquid or soft diet until seen by a Dentist or Oral Surgeon, to avoid chewing in the area of the injured tooth, and to avoid topical analgesics (e.g., oil of cloves) due to the propensity for sterile abscess formation.^{2,4,19} Always warn patients about continued sensitivity. Provide instructions to maintain good dental hygiene, to avoid further trauma, and to follow up with a Dentist or Oral Surgeon for serial examinations.²⁷

Inform the patient and/or their representative what will happen upon follow-up. If a fractured tooth is a primary tooth, the patient usually receives a pulpotomy with removal of the nerve tissue in the crown of the tooth. The primary tooth will be replaced by a permanent tooth. Permanent teeth have a worse prognosis and it should be made clear. Another tooth will not replace the fractured tooth and it will likely receive a pulpotomy. The pulpotomy involves removal of a portion of the nerve tissue followed by sealing the hole. Follow-up is frequent after a pulpotomy to make sure there are no problems involving the root of the tooth.

COMPLICATIONS

Complications of dental trauma include pain, cosmetic deformity, loss of tooth viability, and unsuspected or unrecognized injury to adjacent teeth with later complications. A permanent tooth may develop abnormally in a younger child if injured. Infection can form locally and advance to an abscess, osteomyelitis, and/or systemic infectious complications. Ensuring prompt follow-up with a Dentist can abate the majority of these complications.

SUMMARY

Dental fractures are relatively common traumatic injuries. Appropriate clinical assessment and treatment requires an understanding of basic dental anatomy, terminology, and pathophysiology. Management includes addressing patient discomfort, dental stabilization, and coverage of exposed vulnerable tooth components. Arrange prompt follow-up with a Dentist or Oral Surgeon for definitive care of any dental injury. The Emergency Physician should be ever vigilant for cases suspicious for domestic adult abuse, child abuse, or child neglect.

Temporomandibular Joint Dislocation Reduction

Marilyn M. Hallock

INTRODUCTION

Mandible or temporomandibular joint (TMJ) dislocations usually occur in the setting of prior musculoskeletal problems of the jaw.¹⁻⁵ This includes joint laxity, prior injury or dislocation, inherent hypermobile syndromes (e.g., Marfan's, Ehlers-Danlos), or neuromuscular problems (e.g., dystonic reactions) that pull the mandible out of its joint. The mandibular dislocation typically results from TMJ hyperextension or trauma. The Emergency Physician must be able to reduce a TMJ dislocation. The procedure is easy, simple, and straightforward.

ANATOMY AND PATHOPHYSIOLOGY

The TMJ is an unusual joint (**Figure 216-1**). It is composed of two joints separated by an articular disk.⁶ The TMJ functions as a hinge and gliding joint. A discussion of the mechanics of the TMJ is beyond the scope of this chapter. Anterior dislocations are most commonly seen in the Emergency Department. The etiology of the dislocation includes laughing, chewing, iatrogenic from procedures, opening the mouth wide (e.g., eating, for procedures, yawning, vomiting, singing), seizures, and trauma.⁷⁻¹⁰ These actions can result in the mandibular condyle sliding forward and anterior to the articular eminence of the temporal bone. Anatomic abnormalities of the TMJ have a greater predisposition for mandibular dislocation. These include a shallow articular eminence, weak or torn temporomandibular ligaments, an overstretched joint capsule, previous TMJ dislocations, or hypermobile syndromes (e.g., Marfan's or Ehlers-Danlos syndrome).¹¹ The muscular attachments of the mandible result in a pulling of the condyle superiorly and in front of the articular eminence (**Figure 216-2**).¹⁰ This causes the mandible to become fixed in dislocation and rarely spontaneously reduces.¹²

TMJ dislocations are commonly anterior but may be in any direction.¹³ Anterior TMJ dislocations may occur spontaneously in normal individuals and can occasionally reduce spontaneously. Dislocations of the TMJ can be unilateral or bilateral. Posterior, superior, and lateral dislocations are much rarer. They are seen in the context of direct trauma to the mandible with or without an associated mandible fracture, cervical spine fracture, or skull fracture.^{14,15}

The diagnosis can often be made clinically in a cooperative patient with a nontraumatic history. The patient will present in pain with an open mouth, pain anterior to the ear, protruding mandible, and malocclusion.^{16,17} **A depression, both palpable and visible, will be noted in the preauricular area.**¹⁶ The mandible appears symmetrical in bilateral anterior dislocations and deviated to the opposite side of the dislocation in the case of a unilateral anterior dislocation.¹⁰

Mandibular radiographs are indicated when trauma is involved to rule out an associated fracture. The dislocation is best seen on the Panorex view of the mandible (**Figure 216-3**). TMJ views, if available, are also useful. Computed tomography (CT) scanning (**Figure 216-4**) is warranted if an associated basilar skull fracture, intracranial injuries, or facial fractures are suspected.

INDICATIONS

Attempt to reduce a closed anterior TMJ dislocation without a concomitant mandible fracture in an alert, cooperative, and consenting patient.¹⁸

FIGURE 216-1. Anatomy of the TMJ. **A.** Lateral view of the head and TMJ. **B.** Anatomy of the mandible. **C.** Sagittal section through the TMJ. **D.** The attachment of the muscles of mastication to the mandible. The arrows represent the direction of pull of the muscles.

CONTRAINDICATIONS

Mandibular dislocations that are open, superior in direction, lateral in direction, or posterior in direction require an Oral Surgeon or Otolaryngology consultation prior to reduction attempts. Dislocations associated with mandible fractures require consultation prior

to reduction attempts. The inability to reduce an anterior mandible dislocation by the closed method requires consultation and reduction under general anesthesia. Patients presenting with cranial nerve injuries associated with the dislocation require emergent consultation prior to the reduction.

FIGURE 216-2. Anatomic relationships of the mandible. **A.** The fully opened mandible. **B.** An anterior TMJ dislocation.

FIGURE 216-3. Panorax radiograph of a bilateral mandibular dislocation. Note the mandibular condyle is anterior to the articular eminence of the temporal bone.

EQUIPMENT

- 25 gauge needle
- 3 mL syringe
- Gauze 4×4 squares or rolls
- Gloves
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine
- Equipment and supplies for procedural sedation (Chapter 159)

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient sitting in a multipositional procedure chair with a solid headrest to support their head. Alternatives include placing the patient supine on a gurney or in a chair with an assistant standing behind the patient to stabilize their head (**Figure 216-5**).

The mandible can often be reduced without anesthesia. This is not recommended. **Adequate analgesia and muscle relaxation will**

FIGURE 216-4. Sagittal computed tomography scan image demonstrating the mandibular condyle (arrow) is dislocated anteriorly to the articular eminence (arrowhead). (Used with permission from reference 10.)

FIGURE 216-5. Alternative positioning of the patient.

allow easier manipulation of the mandible back into its anatomic position. Strongly consider the use of parenteral analgesics, sedatives, and/or muscle relaxants. Procedural analgesia and sedation (Chapter 159) may be required to overcome the patient's pain and masticatory muscle spasm. This is especially true to relax the muscles of mastication and allow reduction if the mandible has been dislocated for more than 6 to 8 hours.

An alternative, or adjunct, to the administration of parenteral medications is to inject local anesthetic solution into the TMJ space (**Figure 216-6**). This injection is simple, quick, and relieves significant discomfort. The local anesthetic blocks the pain receptors from the TMJ causing less muscle of mastication spasm. Locate the depression 2.5 cm anterior to the tragus of the pinna and just above the head (i.e., condyle) of the mandible. This is the location of the TMJ space. Clean the skin of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin over the TMJ space and allow it to dry. Insert a 25 gauge needle perpendicular to the skin and directed medially. Advance the needle 0.5 cm and

FIGURE 216-6. Anesthesia of the TMJ. Insert the needle 2.5 cm anterior to the tragus of the auricle and just above the mandibular condyle.

into the TMJ space. Inject 1 mL of local anesthetic solution without epinephrine. Inject the local anesthetic in the subcutaneous tissues as the needle is removed. Inject the contralateral TMJ space if the dislocation is bilateral.

Consider injecting the contralateral TMJ space in a unilateral TMJ dislocation. The patient may experience pain in their contralateral TMJ from muscle spasm due to the increased pressure on it from the contralateral TMJ dislocation. The TMJ injection may reduce some dislocations.¹⁹

TECHNIQUES

CLASSIC OR BIMANUAL INTRAORAL TRACTION TECHNIQUE

The actual reduction requires no specialized equipment beyond nonsterile gloves and gauze 4×4 squares. Position the patient as mentioned previously. Apply gloves and then wrap several layers of gauze around each thumb. **The gauze squares on the thumbs are to prevent possible lacerations to the Emergency Physicians thumbs when the mandible reduces.**

This technique is the most commonly used method to reduce an anterior TMJ dislocation and is described as bimanual intraoral traction.²⁰ Stand or sit in front of the patient (**Figure 216-5**). Place both thumbs into the patient's mouth and onto the most posterior molars of the mandible bilaterally (**Figure 216-7**). Alternatively, place the thumbs on the mandibular ridge immediately posterior to the molars. Wrap the index, middle, ring, and little fingers below the mandible with the index fingers behind the angles of the mandible (**Figures 216-7**). Slowly apply inferior (i.e., downward) and then posterior (i.e., backward) pressure to allow the muscles of mastication to stretch and overcome the muscle spasm (**Figure 216-7**). The downward pressure releases the mandibular condyle from the articular eminence of the temporal bone while manipulating the condylar head and seating it back in the articular glenoid fossa.

Instruct the patient to open their mouth further to relax the elevators of the mandible and to accentuate the deformity. This may disengage the impacted mandibular condyle from the anterior articular eminence of the TMJ. The masseter muscle will cause a rapid and sudden closing of the patient's jaw when the condyle of the mandible snaps back and over the articular eminence.²¹

This classic technique has many disadvantages. It requires much force to reduce the dislocation. The risk of a bite injury to the Emergency Physician is real and might lead to a transmittable disease (e.g., hepatitis, herpes, or HIV). This technique often requires procedural sedation to overcome the muscles of mastication. Repeated attempts may be required to reduce the dislocation.

ALTERNATIVE TECHNIQUES

Numerous alternative techniques have been developed to reduce a TMJ dislocation. They are described below and may work to reduce the TMJ dislocation. Many of these were case reports or a small series of patients. These are too small to make a recommendation and are not endorsed by the author of this chapter and book editor. Nonetheless, they are worth trying.

CORK TECHNIQUE

This technique uses a cork to reduce the TMJ dislocation.^{22,23} Place a cork between the posterior molars on each side. Push up on the mental process of the mandible and use the corks as fulcrums. A cork is hard to find today in the modern hospital. Try a rubber stopper from a test tube as a substitute for the cork. The technique risks the aspiration of the corks or rubber stoppers.

SYRINGE TECHNIQUE

A syringe can be used in place of the cork or rubber stopper.⁹ The size of the syringe will vary based on the ability to fit the syringe in the patient's mouth and the space between the molars. Use as large of a syringe as possible. This technique has a high failure rate with traumatic TMJ dislocations.⁹ Place the syringe as far back in the patient's mouth and between the posterior molars on the dislocated side. Instruct the patient to gently bite the syringe while rolling it back and forth in their mouth. The syringe is used as a rolling fulcrum.

POSTERIOR INTRAORAL TECHNIQUE

The technique requires the Emergency Physician to stand behind the sitting or lying patient.^{24,25} Place inferiorly (i.e., downward) and posteriorly (i.e., backward) pressure on the lower molars (**Figure 216-8**).²⁴ Alternatively, place the thumbs on the retro-molar gums and apply inferiorly (i.e., downward) and anteriorly

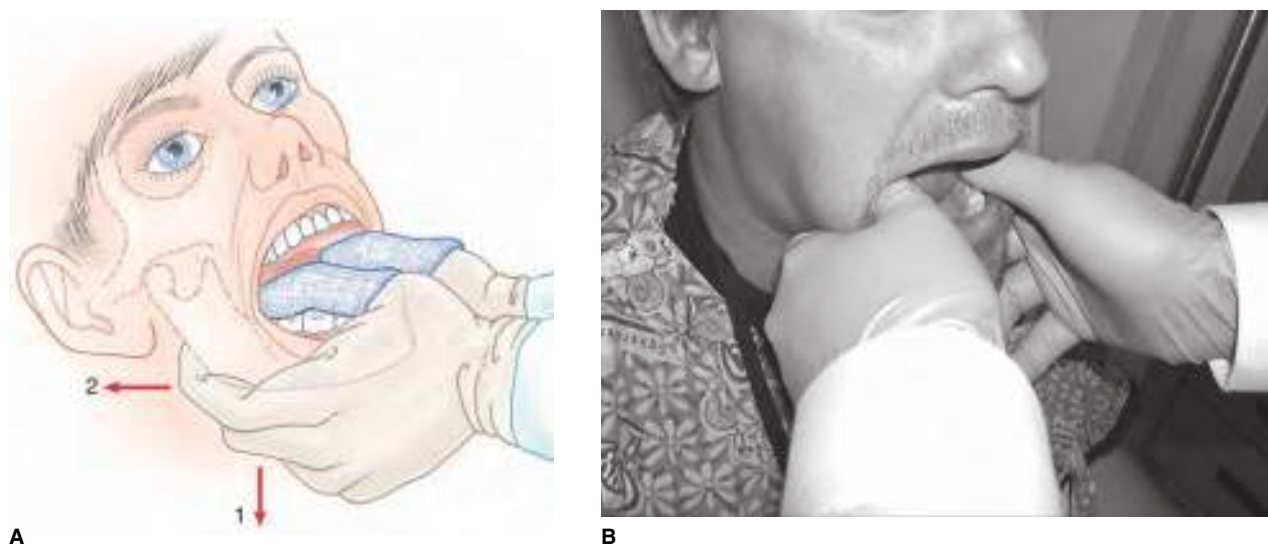

FIGURE 216-7. The classic or bimanual intraoral technique. Proper thumb and hand placement for the reduction of an anteriorly dislocated mandible. **A.** Artist illustration. Apply downward pressure with the thumbs (1) followed by posteriorly directed pressure (2) to reduce the dislocation. **B.** Clinical photo. (Used with permission from reference 4.)

A

B

FIGURE 216-8. An alternative method to perform the classic or bimanual intraoral technique to reduce an anterior TMJ dislocation. **A.** Artist illustration. The patient is supine. Apply inferiorly (i.e., downward) and posteriorly (i.e., backward) pressure on the molars with the thumbs (1) followed by posteriorly directed pressure (2) to reduce the dislocation. **B.** Clinical photo. (Used with permission from reference 4.)

(i.e., forward) pressure on the lower molars.²⁵ This technique has the same disadvantages as listed for the classic technique.

ALTERNATIVE INTRAORAL TECHNIQUE

An alternative technique is to place the thumbs on the buccal aspect of the molars while the patient is sitting or lying. This avoids potential injury to the thumbs when the mandible relocates. It is performed by standing in front of the patient. This method limits the force placed upon the mandible and may not result in a reduction. It is hard to grasp the wet gingiva and the sides of the molars.

GAG REFLEX TECHNIQUE

Inducing a gag reflex with a tongue depressor may relax the spasm of the muscles of mastication and free the condyle and has been used to successfully reduce an anterior TMJ dislocation.²⁶ The mandible snaps back into anatomic position.²⁶ The rapid and forceful snap of the mandible may result in tooth fractures.

UNIFIED HANDS TECHNIQUE

This technique was first described by Cheng.²⁷ Place both thumbs on the occlusal surface of the molars on the dislocated side (**Figure 216-9**). This may allow additional pressure to reduce the

FIGURE 216-9. The unified hands technique to reduce an anterior TMJ dislocation. (Used with permission from reference 27.)

dislocation that is not reduced using the traditional method. This technique has the same disadvantages as listed for the classic technique.

WRIST PIVOT METHOD

The wrist pivot method has been described to reduce a TMJ dislocation (**Figure 216-10**).¹⁶ Wrap the index and middle fingers of both hands with gauze. Place both thumbs under the patient's chin and the wrapped fingers of both hands on the patient's premolars and molars (**Figure 216-10**). Apply upward pressure with the thumbs while simultaneously applying downward pressure on the mandible with the fingers to unlock the mandible and reduce the dislocation. The mandibular angle acts as a fulcrum. This technique has the same disadvantages as listed for the classic technique.

EXTRAORAL APPROACH

An extraoral approach has been described to reduce a TMJ dislocation (**Figures 216-11 and 216-12**).²⁸ The main advantage is the avoidance of hand bites and potential disease transfer. Each TMJ joint is reduced separately.

Place the patient sitting or supine. Stand in front of the patient. Place a hand on each of the patient's cheeks. Place a thumb above the dislocated coronoid process and the fingers of that hand behind the mastoid process. The fingers act as a countertraction force. Place the other thumb over the malar eminence with the fingers of that hand over the angle of the mandible. Pull the nondislocated side anteriorly with the fingers behind the mandibular angle and use the malar-applied thumb as a fulcrum. Simultaneously apply steady posteriorly directed pressure on the dislocated coronoid process until the mandible relocates. The reduction on one side is often followed by spontaneous reduction on the other side.²⁸ This technique is less successful than the traditional technique.²⁸

HIPPOCRATIC TECHNIQUE

The Hippocratic technique involves the mental process pulled inferiorly (i.e., downward) and simultaneously pushing the mandible posteriorly (i.e., backward).^{29,30} There is little information on this technique.

A

B

FIGURE 216-10. The wrist pivot method to reduce an anterior TMJ dislocation. **A.** Artist illustration. **B.** Clinical photo. (Used with permission from reference 4.)

WEDGE METHOD

This method puts wood or cork in between the posterior molars to reduce a TMJ dislocation.³¹ This method may result in tooth fractures.³¹

FIGURE 216-12. The extraoral approach to reduce an anterior TMJ dislocation from behind the patient. (Used with permission from reference 4.)

FORCEPS METHOD

A method was developed using specialized forceps.³² Place the horseshoe-shaped jaws of a forceps between the upper and lower teeth on the dislocated side. Open the jaws of the forceps to force the teeth apart and apply posteriorly (i.e., backward) directed pressure to reduce the dislocation. This method is not recommended for the Emergency Physician.

HOOK REDUCTION

Some consultants openly reduce the dislocation in the Emergency Department. It is usually performed under general anesthesia in the Operating Room with the patient intubated.^{33,34} A small incision is made under the zygomatic arch. The neck of the mandible is grasped with a hook. The hook is pulled to reduce the dislocation. This method is not recommended for the Emergency Physician.

ALTERNATIVE EXTERNAL METHOD

This technique requires a lot of force on the part of the Emergency Physician.³⁵ The patient is placed supine. Stand above the

FIGURE 216-11. The extraoral approach to reduce an anterior TMJ dislocation.

patient's head. Hold the body of the mandible from the opposite side (i.e., under the chin). Instruct the patient to open and close their mouth. Move the mandible up and down in phase with the patient's opening and closing movements. Push on the dislocated condyle with a thumb and simultaneously push it obliquely downward while moving the body of the mandible upward. The dislocated condyle moves over the articular eminence and slips into the fossa.

TONGUE DEPRESSOR TECHNIQUE

Iserson described a technique used by many Oral Surgeons to reduce TMJ dislocations.³⁶ It is a progressive technique using tongue depressors to gradually reduce the dislocation. This technique can be used without anesthesia. Place tongue depressors on top of each other and between the molars on the dislocated side. Insert another tongue depressor when the spasm (i.e., pain) decreases. Keep adding tongue depressors, one at a time, until the dislocation reduces.

GONAI EXTRAORAL AUTOREDUCTION

This autoreduction technique uses the extraoral approach.³⁷ It stands for guided by physicians, opening and closing movements of the mandible, nonstress, autoreduction, and information sheet. This technique involves two steps. The first step is the patient identifying the mandibular condyle using an information sheet. Step two is the patient reducing the mandible. It has the advantages of being easy to explain to the patient, being performed with one hand, and not requiring equipment.

ASSESSMENT

The patient should be able to open and close their mandible without any difficulty after a successful reduction. Postreduction radiographs are not necessary unless a fracture was present or suspected on prereduction radiographs.

AFTERCARE

Refer the patient to an Oral Surgeon or Otolaryngologist within 24 to 48 hours.³⁸ Chronic or recurrent dislocations may require surgical fixation, intermaxillary wiring, surgical alteration of the articular eminence (e.g., eminectomy or eminoplasty), sclerosing of the TMJ, or the injection of botulinum toxin into the lateral pterygoid muscles.³⁹ Instruct the patient to avoid excessive jaw opening (i.e., over 2 cm), to avoid "gummy" foods and hard foods, and to begin a soft diet to avoid excessive strain on the TMJ. Instruct the patient to support their mandible with their hand when yawning so that it does not open widely and dislocate. Nonsteroidal anti-inflammatory drugs will provide adequate analgesia, if needed at all. The application of warm compresses to the TMJ may provide additional pain relief.

A Barton's bandage can be applied around the head to keep the mandibular condyle in its fossa and minimize mandible opening (Figure 216-13). This bandage is often applied for 2 weeks in patients with chronic dislocations or acute recurrences. Only apply a Barton's bandage in consultation with an Oral Surgeon or Otolaryngologist. Patients often do not like this bandage, are noncompliant, and remove it before follow-up. A soft cervical collar can be used to support the mandible and remind the patient to rest their jaw.⁴⁰

COMPLICATIONS

Complications of the initial injury include fractures, intrusion of the mandibular condyle into the external auditory canal (i.e., posterior dislocation) or basal skull (i.e., superior dislocation), cerebral

FIGURE 216-13. The Barton bandage.

contusions, facial nerve injuries, and middle or inner ear injuries with hearing and balance impairments. Recurrent dislocations are possible in the future after the mandible has been dislocated once.

The reduction technique is rarely associated with complications. Significant pain after a successful reduction may signify a fracture or articular cartilage avulsion. Fractures are rarely iatrogenic. They are often present on initial radiographs but not identified until retrospectively examined. A fracture may be displaced during the reduction. The Emergency Physician's thumbs can be crushed and/or lacerated by the patient's teeth.

Closed reduction may be unsuccessful. The patient will require reduction under general anesthesia. This is particularly true of chronic dislocations, dislocations for longer than 12 hours, and recurrent dislocations.^{41,42} An avulsed articular cartilage or articular disc may be interposed and prevent closed reduction.

SUMMARY

Uncomplicated anterior mandible dislocations can be managed with basic anesthesia and sedation techniques. A gentle and progressive reduction will allow the mandibular condyle to relocate into the TMJ space without significant complications. Dislocations that are complicated by fractures or by overlying skin damage, that are nonanterior in location, or that have associated neurologic injuries require an emergent consultation and reduction by an Oral Surgeon or an Otolaryngologist.

Arch Bar Separation

Richard Dean Robinson, Amanda Catherine Pientka,
and Phuc Ba Duong

INTRODUCTION

The evaluation and management of the airway is a crucial component of any critically ill medical or trauma patient. Any airway has the potential to be challenging. Certain situations complicate our standard approach to securing the airway and warrant attention. Mandibular and maxillofacial trauma complicate the standard approach to securing an airway. Patients presenting with hardware in place due to previous mandibular and/or maxillofacial fixation and requiring airway protection and/or intubation represent a potentially challenging situation. The technique for emergent mandibular and/or maxillofacial fixation release to facilitate airway rescue will be discussed in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Dental anatomy differs between pediatric and adult populations (Chapter 215). Variations among individuals are not uncommon. The basic anatomy of a tooth consists of the crown covered with enamel which sits above the gum line. The tooth root is embedded in the alveolar bone. The fully formed root apex present in adult patients consists of alveolar bone, periodontal ligament fibers, and the cementum cell layer.

The musculoskeletal anatomy of the mandible and maxilla is shown in **Figure 216-1**. Fractures of the mandible and/or maxilla can occur at several different locations (e.g., alveolar ridge, alveolar process, body, angle, and symphysis). The mandibular condyle interacts with the articular fossa of the maxilla to form the temporomandibular joint. The zygomatic process connects to the body of the maxilla superior to the alveolar process. Mandibular or maxillofacial trauma can cause instability at any of these sites.

Mandibular fixation with arch bars consists of a series of wires. These wires run horizontally across the alveolar bone of the mandible and maxilla to fixate and stabilize the dental arches (**Figure 217-1**). There are also vertical wires connecting the maxilla and mandible to eliminate any mandibular opening and closing motion (**Figure 217-2**). Cut the vertical fixation wires in the setting of airway compromise to facilitate emergent airway access or significant vomiting that may result in aspiration. The horizontal running arch bars are not involved in jaw separation and should be left intact.

The fixation technique (i.e., arch bars) used to stabilize mandibular and maxillary fractures carries a significant associated expense.¹ This depends on the facility and specialist placing the hardware. The mean total charges can range from \$13,000 to over \$25,000. It can take between 0.6 to 1.4 hours to place arch bars depending on the specific injury.

INDICATIONS

The decision to remove the hardware calls for careful consideration of the urgency of the patient's presenting symptoms.² The indications for emergent arch bar separation include the need for

FIGURE 217-1. Arch bar horizontal fixation apparatus. (Photo courtesy of Phuc Ba Duong, DDS.)

emergent access to airway, vomiting with the potential for aspiration, or aspiration.

CONTRAINDICATIONS

There are no absolute contraindications to the separation of standard wired arch bars. Consider a surgical airway if arch bars are severely damaged and prohibit the proper separation of the patient's jaws and a patient's airway is an immediate concern.

FIGURE 217-2. Arch bar complete horizontal and vertical fixation apparatus. (Photo courtesy of Phuc Ba Duong, DDS.)

A

B

FIGURE 217-3. The wire cutters. **A.** Standard version from the maintenance department or a hardware store. **B.** A sterilizable hospital wire cutters.

EQUIPMENT

- Wire cutters
- Hemostat
- Bone wax, optional
- Sterile 2×2 gauze squares
- Frazier suction catheter
- Suction source and tubing
- Light source, overhead or headlamp

Several sources are available for the wire cutters. The maintenance department may be contacted to borrow wire cutters (**Figure 217-3A**). The Operating Room or central supply can be contacted for sterile wire cutters (**Figure 217-3B**). These are no help due to the delays involved if the wire cutters are needed emergently. It is recommended to keep a pair of wire cutters in a secure location within the Emergency Department for easy access and use in an emergency.²

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent for the procedure from stable patients. Document that an emergent procedure was necessary when unable to obtain informed consent due to impending airway compromise. Place the patient on a monitor. Insert and secure a large-bore intravenous catheter to facilitate parenteral medication administration and as a precursor to advanced airway management should the need arise. Medication to prevent nausea

FIGURE 217-4. Cutting of the vertical wires (pink arrow) connecting the maxilla and mandible. (Used with permission from reference 2.)

may be useful. Be prepared to roll the patient onto their side to avoid complications (e.g., aspiration). Consider the use of local anesthetic in patients experiencing pain (Chapter 209). Use an overhead light or a headlamp to provide adequate illumination.

TECHNIQUES

Clamp the middle of the vertical wire with a hemostat for safety. Use a pair of wire cutters. Clip the vertical fixation wires in two places (**Figure 217-4**). Cut the wire near the attachment to the maxillary and mandibular arch bars. **Do not cut the horizontal arch bars or wires. They are not involved in jaw separation and should be left intact.** Remove the hemostat and cut wire. Cutting the wires from the maxilla to the mandible permits jaw opening, facilitates access to the airway, and allows the patient to expel any oral contents (e.g., vomitus).

PEDIATRIC CONSIDERATIONS

Pediatric patients may or may not be treated with conventional arch bars depending on their age. Children from ages 6 to 12 often have mixed dentition. Use caution when evaluating children in the setting of any dental or maxillofacial trauma.³

ASSESSMENT

Secure the airway and address the emergency after cutting the wires. Inspect the oral cavity for retained wires, broken dentition, and foreign bodies. Damage to oral structures or the arch bars may have

occurred if the patient sustained trauma while the arch bars were in place.

AFTERCARE

Ensure no sharp edges from cutting the vertical wires that can cause injury to the patient. Cut these sharp wires or cover them with bone wax. Consult the Oral Maxillofacial Surgeon, Otolaryngologist, or Plastic Surgeon who placed the arch bars. Discuss the replacement of vertical wires after the emergency has been stabilized or resolved, whether additional operative interventions or procedures are required, and any additional care. Ensure adequate follow-up if the patient is discharged from the Emergency Department and provide appropriate analgesia.

COMPLICATIONS

Exercise caution while separating and cutting the wires. Cut wires can puncture gloves, puncture or cut skin, and potentially transmit infection. Use care to minimize iatrogenic trauma during arch bar separation. Approach wire cutting as if the wires and wire cutters were sharp needles. The patient can receive intraoral punctures or cuts from the wire cutters or the cut wires. Routine plain radiography is not indicated in the setting of arch bar removal.⁴

The cutting of wires can result in pieces of the wire being aspirated or lost. Clamping the vertical wire with a hemostat before cutting can prevent this. **Ensure the removal of the cut wire if not using a hemostat.** Obtain a Panorex or bilateral mandible radiographs to evaluate for missing wires. Obtain chest and abdomen radiographs if the dental radiographs are negative. The missing fragment seen on radiography requires an emergent consult with the appropriate specialist for removal.

SUMMARY

Patients with arch bars present a unique challenge to the Emergency Physician. Arch bars limit the ability to evaluate and access the airway. The cost of mandibular fixation is significant. The decision to remove or separate vertical wiring must be weighed against the urgency of the patient's presentation. Identification of the proper wires to cut are vital in a situation where immediate lifesaving action is undertaken. Wire cutters should be readily available in the Emergency Department for use in these situations. Care should be taken during and after arch bar separation to prevent injuries from the wire cutters and cut wires. Handle the wires as if they were needles. Examine the patient for loose hardware or foreign bodies. Arrange adequate consultation and follow-up.

Ingrown Toenail Management

Sean Dyer and Jeff Schaidler

INTRODUCTION

An ingrown toenail (onychocryptosis) is a common affliction that can occur in any toe. It most commonly afflicts the great toe, occurring when the lateral edge of the nail plate penetrates the soft tissue of the lateral nail fold. There are three stages of ingrown toenails.¹ Stage I includes erythema, slight edema, and pain when pressure is applied to the lateral nail fold. Stage II includes the stage I findings plus signs of infection and a purulent drainage. Stage III is a magnification of the two previous stages with the addition of granulation tissue formation and lateral nail fold hypertrophy. Most ingrown toenails can be definitively managed in the Emergency Department by the Emergency Physician.

ANATOMY AND PATHOPHYSIOLOGY

The toenail usually does not grow into the soft tissue. Instead, the soft tissue overgrows and obliterates the nail sulcus in response to external pressure and irritation.²⁻⁶ The toenail itself is usually normal, although some older patients may have incurved nails. The causes of an ingrown toenail are multiple and include trimming the toenails too short, using sharp tools to clean the toenail gutters, wearing improperly fitted (i.e., too tight) shoes, rotated digits, and bony deformities. Improper toenail trimming can result in a small nail spike on the lateral aspect of the toenail (Figure 218-1). As the toenail continues to grow, the spike will irritate the soft tissue causing the end result of chronic inflammation and an infection.

INDICATIONS

Warm soaks, oral antistaphylococcal antibiotics, and shoes with an adequate toe box may be curative in mild cases (stages I and II). Elevate and maintain the nail edge above the soft tissues or trim the edge of the nail (Figure 218-2). More severe cases (stage III) require partial toenail removal. For those with incurved toenails or abnormally wide toenails, partial nail avulsion and phenol treatment are usually indicated as simply instructing on proper toenail cutting is not sufficient.⁷ When caused by nail spikes from improper nail trimming, usually in younger populations, these infrequently require partial nail removal and can be treated conservatively with instruction on proper nail trimming and proper fitting shoes. Have a lower threshold for toenail removal in diabetic patients to prevent a more severe infection from forming. Other indications for removal of an ingrown toenail include chronic or recurring ingrown toenails, failure of conservative therapy, fungal infections of the toenail, and severe pain.

A

B

FIGURE 218-2. Management of stage I and II ingrown toenails. **A.** Trimming the lateral nail edge. **B.** Elevation of the lateral nail edge.

CONTRAINDICATIONS

The only relative contraindication to toenail removal is a decreased vascular supply to the toe. Trim the toenail edge if possible and minimize any injury to the adjacent soft tissues. These patients require an evaluation by a Podiatrist and a Vascular Surgeon to minimize future complications.

EQUIPMENT

■ GENERAL SUPPLIES

- Povidone iodine or chlorhexidine solution
- Sterile drapes
- Sterile gloves
- Curved hemostat
- Freer or another periosteal elevator
- Cotton
- Scissors or nail splitter
- Tourniquet or sterile Penrose drain
- Curette
- Topical antibacterial ointment
- 4×4 gauze squares
- Tape, 1 inch wide

■ CHEMICAL MATRIX ABLATION

- Above listed general supplies
- Cotton-tipped applicators
- 89% phenol solution
- 70% isopropyl alcohol solution
- Silver nitrate matchsticks

■ SURGICAL MATRIX EXCISION

- Above listed general supplies
- #15 scalpel blade on a handle
- Needle driver
- 5-0 nylon suture

■ NAIL MATRIX CAUTERIZATION

- Above listed general supplies
- Electrocautery unit, disposable

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Obtain an informed consent for the procedure. Place the patient supine on a gurney or procedure table. Flex the patient's hip and knee so that the plantar surface of their foot is flat against the gurney. An overhead light source is essential to provide appropriate illumination. Perform a digit block using aseptic technique. Refer to Chapter 156 regarding the details of digital anesthesia. Although rare, an occasional nervous or uncooperative patient may require an intravenous anxiolytic or even procedural sedation prior to the digital anesthesia. The young child will require physical restraint with a sheet or commercial device (e.g., Papoose board) and procedural sedation. Apply povidone iodine or chlorhexidine solution over the involved toe and allow it to dry. Apply a sterile drape to delineate a sterile field.

TECHNIQUES

Manage early ingrown toenails (stages I and II) with conservative therapy with simple trimming of the distal nail or elevation of the nail. Remove the medial or lateral one-quarter of the toenail along with the germinal matrix at the base of the toenail for stage III ingrown toenails. The entire nail may be removed if both sides are ingrown. It may be necessary to prevent any new nail growth in the area once the nail has been removed. Three options include chemical ablation of the matrix, surgical excision of the matrix, and electrocautery of the nail matrix.¹ There is a recurrence rate of less than 5% when using the excision and phenol method.⁷ This is the most effective treatment in a recent clinical review.⁷ When the ingrown toenail is caused from hypertrophy of surrounding tissue, a referral to a Podiatrist is indicated for a debulking treatment. The treatment of the pediatric patient is no different than that of the adult patient.^{6,7}

TOENAIL ELEVATION AND TRIMMING

Ingrown toenails in the first two stages can be trimmed or elevated to relieve the patient's symptoms (**Figure 218-2**). Trim the distal edge of the nail plate to remove the ingrown portion (**Figure 218-2A**). Remove the distal one-third to one-half of the nail plate. Smooth the nail plate edge so that it will grow out freely. Remove any debris along the lateral nail fold (i.e., the paronychia) or nailbed.

An alternative is to elevate the edge of the nail plate (**Figure 218-2B**). Insert the jaws of a hemostat so that one is above and the other is below the ingrown nail edge. Clamp the jaws of the hemostat onto the nail plate. Slowly rotate the hemostat up and away from the ingrown side to elevate the edge of the nail plate above the adjacent soft tissues (**Figure 218-2B**). Insert a wad of cotton under the nail edge to maintain it above the adjacent soft tissues. Release the hemostat. Teach the patient and/or their representative this technique so that they can replace the cotton wad daily until the nail plate grows out and past the soft tissues. The main disadvantages of this technique are that the patient or their representative must elevate the nail edge and replace the cotton daily as well as maintain the nail plate elevation for 3 to 6 weeks. This can be quite a challenge, if it is even possible, in the young child.

TOENAIL REMOVAL

Apply a tourniquet along the base of the afflicted toe (**Figure 218-3A**). The tourniquet may be a commercially available product for the digits or a Penrose drain. Refer to Chapter 129 for several examples of digital tourniquets. Separate the nail from the underlying nail bed. Grasp and stabilize the toe with the nondominant hand. If available, use a Freer periosteal elevator to lift the soft tissue off the lateral and proximal toenail. The elevator can also be used to separate the nail plate from the underlying nail bed, but this is optional. Insert one jaw of a curved hemostat under the distal toenail margin and along the medial or lateral side of the nail plate, depending upon which side is ingrown (**Figure 218-3B**). Advance the hemostat until the jaw is at the proximal corner of the involved side of the ingrown nail (**Figure 218-2C**). Grasp the nail by clamping the jaws of the curved hemostat on the toenail.

Dislodge the ingrown nail from the skin, the nail bed, and the nail matrix by rotating the hemostat away from the ingrown portion (**Figure 218-3D**). Continue to rotate the hemostat until the entire ingrown portion of the nail is separated from the skin, the nail bed, and the nail matrix. A large and complete portion of the underlying toenail will emerge from under the skin fold (**Figure 218-3E**). The nail plate might have broken and a significant piece may still be under the inflamed skin border if only a small amount of the nail is visible after rotating the hemostat. Expose this area and use the curved hemostat to remove any remaining nail plate.

FIGURE 218-3. Ingrown toenail removal. **A.** Placement of a tourniquet. **B.** Place one jaw of the hemostat above the nail plate and one jaw beneath the nail plate. **C.** Advance the hemostat toward the base of the nail plate. **D.** Rotate the hemostat to elevate the edge of the toenail. Be sure to elevate and expose the proximal nail segment at the base of the nail in the region of the nail matrix. **E.** Determine where to cut the nail plate. **F.** Cut the nail plate with a heavy scissors or a nail splitter. **G.** The lateral one-fourth of the nail plate has been removed. **H.** The granulation tissue has been trimmed away.

Cut away the ingrown portion of the toenail, from distal to proximal, down to the nail plate in a straight line with a heavy scissors or nail splitter (**Figure 218-3F**). **Make sure that the points of the scissors or nail splitter are facing upward to prevent injury to the nail bed.** The granulation tissue overlying the nail bed must be removed to prevent another ingrown toenail (**Figure 218-3G**). Trim the granulation tissue using a #15 scalpel blade or a curette (**Figure 218-3H**). Remove the tourniquet and control any bleeding.

Some Emergency Physicians prefer to perform the above described procedural steps in a slightly different order. They cut away the ingrown portion of the toenail before dislodging the remainder of the toenail. This is left to physician preference.

CHEMICAL NAIL MATRIX ABLATION

Chemical ablation of the nail matrix with phenol has several advantages.^{1,8,9} The procedure is easy, quick, and simple to perform. No special equipment is required. The use of an incision or electrocautery and their associated complications is avoided.

Chemical ablation of the matrix with phenol is the author's preferred method. Remove the ingrown part of the toenail as described above. Remove any obvious remaining nail matrix and nail bed with a blunt instrument such as a curette. **Completely dry the field of any blood and fluid.** Dip a cotton-tipped applicator in a phenol solution. **Avoid excessive saturation of the swab.** Introduce the swab between the roof and the root matrix (i.e., under the eponychium) of the removed nail section (**Figure 218-4**). Rotate the cotton-tipped applicator slowly for 30 seconds in adults and 20 seconds for children. Remove the cotton-tipped applicator. Repeat the phenol application two additional times using a fresh phenol-soaked cotton-tipped applicator. **Do not allow the phenol to contact normal skin.**¹⁰ **Immediately wipe off any phenol that contacts the skin.** The phenol will turn the tissue pale or gray. Dip a cotton-tipped applicator in isopropyl alcohol. Swab the area in similar fashion as the phenol swab. The isopropyl alcohol neutralizes the necrotizing effect of the phenol.⁸⁻¹¹

An alternative to phenol is silver nitrate. The preferred technique is a phenol matrixectomy. Silver nitrate may be used if phenol is not available. The main disadvantage of silver nitrate is that it turns the tissues black. Insert the silver nitrate matchstick under the eponychium (**Figure 218-4**). Roll the matchstick around for 5 to 10 seconds to ablate the matrix.

SURGICAL NAIL MATRIX ABLATION

Surgical excision of the toenail matrix requires more time and experience than chemical ablation.⁵ This technique is usually reserved for the Podiatrist or the Orthopedic Surgeon. An experienced

FIGURE 218-4. Chemical nail matrix ablation.

FIGURE 218-5. Surgical nail matrix ablation. **A.** An incision in the eponychium to expose the matrix. **B.** Removal of the matrix. The pink shading represents the areas of tissue to be removed.

Emergency Physician can easily perform this technique in the Emergency Department.

Remove the ingrown part of the toenail as described above. Expose the nail matrix by retracting the adjacent overlying skin. Make an oblique proximal incision from the proximal corner of the nail if necessary to fully expose the nail matrix in the ingrown area (**Figure 218-5A**). Make an incision with a #15 scalpel blade to separate the nail matrix to be removed from the remaining nail and matrix (**Figure 218-5B**). Grasp the corner of the matrix with a hemostat. Use the scalpel blade to separate the matrix from the underlying tissues. Remove the nail matrix. Do not forget to remove the dorsal and deep matrix that envelops the base of the toenail under the skin fold. Remove any remaining nail matrix and nail bed with a curette. Close the skin incision with 5–0 nylon suture.

ELECTROCAUTERY NAIL MATRIX ABLATION

Electrocauterization of the nail matrix is rapidly performed but requires access to an electrocautery instrument. Apply electrocautery between the roof and the root matrix of the removed nail section to destroy the matrix in this area. Avoid excessive burning of the surrounding tissues. This technique can cause significant damage to normal tissue and should be reserved for the Podiatrist or the Orthopedic Surgeon.

AFTERCARE

Apply a topical antibiotic ointment and a small compressive gauze dressing over the toe. The patient requires follow-up in 24 to 48 hours for a dressing change and evaluation of the wound. Saturate the dressing with saline or sterile water to make the removal process less painful. Instruct the patient to elevate the foot for the first 2 to 3 days to prevent bleeding and edema. Large shoes, sandals, or cast shoes are best used in the immediate postprocedure days. The use of oral antibiotics is restricted for patients who are immunocompromised, have an associated cellulitis, have a postprocedure infection, or whose vascular supply to the toe is decreased. Prescribe nonsteroidal anti-inflammatory drugs supplemented with narcotic analgesics as needed for pain control. Instruct the patient to return to the Emergency Department immediately if they experience increased pain, develop a fever or a purulent discharge, or notice increased redness of the toe or foot. Demonstrate the proper method to trim toenails (**Figure 218-6**).

Chemical ablation of the matrix with phenol induces a chemical burn.¹⁰ The patient may experience a serous drainage for a few days up to 2 weeks.² The use of nonsteroidal anti-inflammatory drugs can limit the duration and the amount of drainage.² Instruct the patient to soak the foot in warm water three times a day for 10 to 15 minutes each time. Apply a topical antibiotic ointment after each

soak. Prolonged drainage may be due to a superficial infection and requires evaluation.

COMPLICATIONS

The most common complication is the persistence of toenail horns or spikes due to incomplete ablation of the nail and matrix. These can be managed with nail trimming if mild or en bloc excision of the area if severe. Ensure that the portion of the nail is completely removed and that no fragments remain under the nail folds. Use care to not lacerate the nail bed when elevating or cutting the nail plate. Lacerations of the nail bed can bleed significantly, cause chronic pain once healed, and result in a deformed nail. Repair any nail bed lacerations. Refer to Chapter 129 for a complete discussion regarding nail bed repair.

Phenol will deteriorate if it is exposed to air or light. Store the phenol solution in a cool, dark place. Replace the solution frequently. The field must be dry before applying phenol. Phenol mixed with blood results in an alteration of the pH of the phenol, decreasing its effectiveness and turning the tissues black. The ingrown toenail will recur if the phenol is old or exposed to light before it is used, if the phenol is not properly applied, or if fragments of the toenail or matrix remain. The patient may experience a chemical burn if too much phenol is applied or it is not neutralized with isopropyl alcohol.

SUMMARY

An ingrown toenail can be managed easily, quickly, and definitively in the Emergency Department. Perform a partial toenail removal on patients with clinical stage III toenails characterized by pain,

FIGURE 218-6. The technique of toenail trimming. **A.** Correct. **B.** Incorrect.

overgrowth of inflamed and infected tissue, and drainage. Remove the lateral or medial one-quarter of the nail. Apply phenol solution to the nail matrix to prevent further growth of the nail and a recurrence.

Plantar Puncture Wound Management

Vishal Bhuva and Dhara Amin

INTRODUCTION

Plantar puncture wounds are frequently encountered in the Emergency Department (ED).¹ They account for approximately 7% of patients presenting to the ED with lower extremity trauma.² Wounds are more likely to occur in the warmer summer months from May through October when people spend more time outdoors and barefoot. Nails produce the majority of puncture wounds followed less commonly by wood, glass, and other metal objects.²⁻⁵ Patients seek medical treatment following puncture wounds for many reasons including tetanus immunization, pain relief, retained foreign bodies, and treatment of established infections.

There are very little data regarding the proper management of plantar puncture wounds but it is clear that complications can and do arise.¹⁻¹⁷ Infection and retained foreign bodies remain the most serious of these complications. The true risk of infection and osteomyelitis remains unknown. Rates of infection are estimated to be in the range of 6% to 11%, with only a fraction of these complications proceeding to osteomyelitis.^{2,4} Risk factors for the development of infectious complications have been identified and include puncture wounds to the forefoot, punctures through rubber-soled shoes, deep penetration, and diabetics (particularly those with neuropathy).^{6,7}

One of the difficulties in reporting the incidence of plantar puncture wounds is that patients do not always present to the Emergency Department. Most patients remove the offending foreign body and

never seek medical treatment. They present to the ED when there is a suspicion of a retained foreign body or an infection.⁸ Despite the high frequency with which Emergency Physicians are faced with patients who have sustained a plantar puncture wound, there is no standard of care for treating these injuries. The pathophysiology and management of plantar puncture wounds are dependent on a host of factors including the location of the wound, the penetrating material, the depth of penetration, the footwear at the time of injury, the time to presentation, and any concomitant illnesses. This chapter summarizes the approach to the management of the plantar puncture wounds.

ANATOMY AND PATHOPHYSIOLOGY

The foot is a complex structure (**Figures 219-1 and 219-2**). The plantar surface is composed of the skin and a thin subcutaneous layer. The skin has a thickened stratum corneum layer making it one of the thickest areas of epidermis in the body. This thickened epidermal layer gives the plantar surface protection against mechanical forces. The plantar aponeurosis extends over the base of the foot and forms the plantar fascia. Deep to the fascia are various muscles and tendons with their sheaths. The longitudinal arch of the foot extends from the metatarsal heads to the calcaneus. The dorsal surface of the foot has a thin skin layer without much subcutaneous tissue. Under the thin subcutaneous layer is the superior dorsal fascia and the dorsal aponeurotic layer which encompasses the extensor tendon sheaths.

The thickened plantar epidermal layer prevents minor mechanical insults from penetrating the skin. An object can puncture the plantar surface of the foot and compromise the deeper layers of the foot. The impaling object may just breach the plantar fascia or even go through the foot depending on the depth of penetration. Puncture wounds occurring over the metaphalangeal joints are associated with greater complications as they often involve the joint spaces.^{9,10}

The most common organisms causing soft tissue infections are *Staphylococcus* and *Streptococcus*. However, when osteomyelitis or osteochondritis occurs from a puncture through the sole of the shoe, *Pseudomonas* is the most frequent causative agent.^{2,9} Studies have shown that *Pseudomonas* lives in actively used shoes and will enter the avascular cartilage layers of the foot during a puncture through a shoe.⁹

INDICATIONS

Determine if the penetrating object is small, such as a needle or pin, and if a portion may still be within the foot. If the patient was able to remove the object intact, no further treatment is required. The patient may be discharged with appropriate wound care instructions and asked to return if there are any signs of an infection. **Obtain soft tissue radiographs if the impaling object is broken off or the possibility of a retained foreign body exists.** Whereas metallic and glass foreign bodies are visible on plain radiographs, wood and plastic foreign bodies are generally not.^{11,12} They require evaluation by ultrasound, computed tomography (CT) scanning (**Figure 219-3**), magnetic resonance imaging (MRI), or wound exploration.^{2,3,5} Ultrasound continues to emerge as a powerful bedside tool for Emergency Physicians (**Figure 219-4**). However, the dense tissue planes of the foot limit its usefulness in detecting plantar foreign bodies.¹¹ **Blind wound exploration, blind probing, and blind irrigation are no longer supported.** These techniques have never been shown to improve outcomes, they are painful, and they are potentially harmful. A sample algorithm for penetrating objects is noted in **Figure 219-5**.

FIGURE 219-1. The anatomy of the foot in midsagittal section.

CONTRAINDICATIONS

Evidence of deep penetration, extensive penetration, or multiple retained foreign bodies should be evaluated in consultation with a Podiatrist or Orthopedic Surgeon. Additionally, manage patients who present more than 72 hours after the injury with evidence of

an infection while taking antibiotics, a draining tract, or dorsal foot symptoms (e.g., erythema, pain, or swelling) in consultation with a foot specialist.^{5,8,12} Surgical exploration and irrigation are required for penetration of any joint space or wounds overlying the metatarsal heads. Do not explore plantar puncture wounds if you are not experienced in or comfortable with the procedure.

FIGURE 219-3. An example of a CT scan showing a wood foreign body in the left foot (arrow). (Used with permission from Schwartz DT: *Emergency Radiology: Case Studies*. New York: McGraw-Hill; 2008.)

FIGURE 219-4. An example of an ultrasound scan showing a wood foreign body in the foot (arrows). (Used with permission from Dean AJ, Gronczewski CA, Costantino TG. Technique for emergency medicine bedside ultrasound identification of a radiolucent foreign body. *J Emerg Med* 2003;24(3):303-308.)

EQUIPMENT

- Povidone iodine solution
- 10 mL syringe
- Local anesthetic solution with or without epinephrine
- 23 to 27 gauge needle
- 4×4 gauze squares
- Eye protection or splash guard
- Gloves
- 15 mL syringe
- Sterile normal saline for irrigation
- 18 gauge plastic angiocatheter without the needle
- Surgical scalpel blades, #11 and #15, on a handle
- Cuticle clippers or fine iris scissors
- Curved mosquito hemostat
- Blunt probe
- Toothed forceps
- Circular corn pad
- Tubular cling
- Tape, 1 inch wide

PATIENT PREPARATION

Assess every patient with a puncture wound individually. Determine whether the penetrating object remains embedded in the foot and the cleanliness of the object. Was it contaminated or rusty? Identify the site of the incident. Was it outdoors or indoors? What type of footwear was worn at the time of the incident? Where in the foot is the puncture wound? Estimate the depth of penetration. Ascertain if the patient has any comorbid health conditions that may affect wound healing.⁶ Does the patient need tetanus immune globulin (TIG) or a tetanus booster? If the patient has received less than three doses of tetanus toxoid, they should be given tetanus booster and TIG.⁹

Obtain plain soft tissue radiographs or a bedside ultrasound if there is suspicion of a retained foreign body, if an infection is present, if the patient presents more than 72 hours after incurring the injury, if the patient stepped on glass, or if the patient feels that a foreign body is present. Glass is radiopaque and visible upon plain radiographs.^{6,8-12} The patient is often correct if they have a foreign body sensation and feel that a foreign body is “still there.”¹²

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Obtain a signed informed consent for the procedure. Place the patient supine or prone on a gurney. Remove any superficial foreign bodies. Clean the skin overlying the wound of any dirt and debris. Clean the skin posterior to the medial malleolus if a posterior tibial nerve block is to be performed. Apply povidone iodine solution to the skin and allow it to dry. Apply sterile drapes to delineate a sterile field.

Anesthetize the area with a posterior tibial nerve block if exploration and retrieval are indicated (**Figures 219-5 and 219-6**). Do not inject directly into the plantar surface of the foot. Perform a posterior tibial nerve block if anesthesia is required.⁵ The posterior tibial nerve is superficial at the ankle midway between the medial malleolus and the heel (**Figure 219-6**). It lies between the tendons of the flexor digitorum longus and flexor hallucis longus muscles. It travels with and slightly posterior to the posterior tibial artery. The posterior tibial nerve divides at the inferior border of the calcaneus to form the medial and lateral plantar nerves which provide motor innervation to the intrinsic foot muscles. The lateral plantar

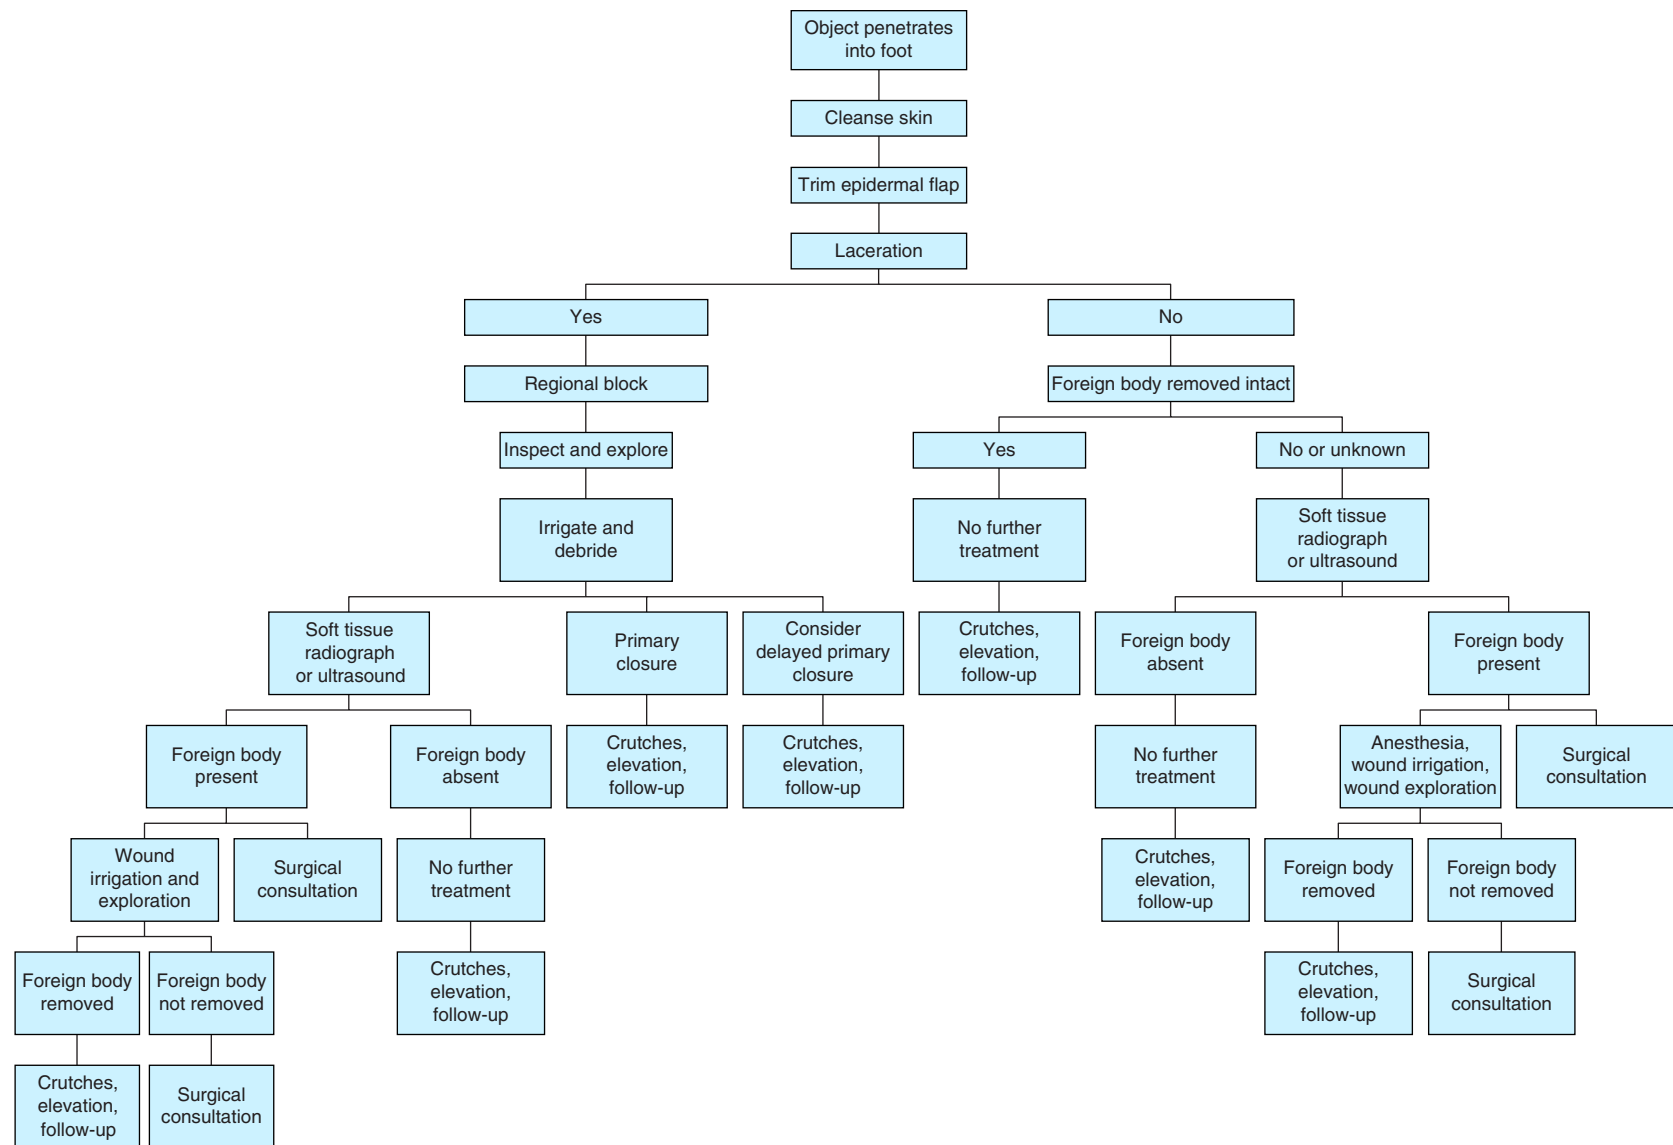

FIGURE 219-5. An example of a management algorithm for plantar puncture wounds. (Adapted from references 4 and 13.)

A

B

FIGURE 219-6. The posterior tibial nerve block. **A.** The course of the posterior tibial nerve. **B.** Needle insertion and direction.

nerve provides sensory innervation to the lateral one-third of the sole and plantar surface of the lateral 1½ toes (**Figure 156-27**). The medial plantar nerve provides sensory innervation to the medial two-thirds of the sole and the plantar surface of the medial 3½ toes (**Figure 156-27**).

Place the patient supine with the ankle supported on a pillow or blanket and the leg externally rotated. Identify, by palpation, the medial malleolus and the posterior tibial artery by its pulsation. Place a skin wheal of local anesthetic solution at the level of the upper border of the medial malleolus and just posterior to the posterior tibial artery or medial to the Achilles tendon. Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 156-40**). Advance the needle to the tibia or until paresthesias are elicited. If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, infiltrate 5 to 7 mL of local anesthetic solution starting against the posterior tibia as the needle is withdrawn.

TECHNIQUES

After cleaning the area carefully, debride any devitalized skin and callused edges of the stratum corneum overlying the wound with a pair of fine scissors or cuticle clippers. Obtain a culture swab of the wound if there is any evidence of infection.

It is often difficult to determine whether a joint space has been breached by the foreign body. Assume any puncture wound in the metatarsophalangeal joint area involves a joint space and consider consulting a Surgeon. Try to remove a foreign body within the wound. Avoid extensive exploration to prevent secondary injury to a joint space or tendon sheath. Refer deeply embedded foreign bodies to a Surgeon for exploration and removal in the Operating Room. Consider conservative therapy in patients presenting within 24 hours of the injury without preexisting impediments to wound healing or wound assessment.^{4,9} Clean the area locally and keep patients non-weight bearing for 24 hours with follow-up within 48 hours.

AFTERCARE

Apply a donut-shaped corn pad around the puncture site. Apply topical antibiotic gel followed by a gauze dressing. The gauze may be held in place with tubular gauze or a gauze roll wrapped about the foot.

The use of prophylactic antibiotics is controversial. **There is no good evidence supporting the use of prophylactic treatment of plantar puncture wounds with antibiotics.**^{4,6,8,9} Physician discretion is advised. Certain at-risk groups or injuries (e.g., diabetics, wounds over metatarsophalangeal joint, immunocompromised, or deep wounds) may be appropriate for treatment, although evidence is lacking even in these high-risk groups. Institute empiric antibiotic coverage for *Staphylococcus* and *Streptococcus* if this is a late presentation and there is evidence of cellulitis. Prescribe penicillinase-resistant antibiotics for 7 to 10 days guided by sensitivities. Patients who have diabetes or who are immunocompromised require broad-spectrum antibiotics, such as a third-generation cephalosporin or quinolone, and close follow-up. Consider antibiotic coverage that includes that for methicillin-resistance *Staphylococcus aureus*.

Patients who present more than 24 hours after a puncture wound need to be assessed for the retention of a foreign body.¹⁴ If they fail a course of outpatient antibiotics, they require a full work-up to rule out osteomyelitis and a deep foreign body, not just a change to a new antibiotic. One study looking at pediatric puncture wounds advised that all children with an established infection 24 to 36 hours after a plantar puncture wound should be admitted for parenteral antibiotics.¹² They found that delayed presentation is significant for deep-seated infection. **Further infection or relapse after an initial treatment is suspicious for a retained foreign body or osteomyelitis.** A bone scan and an erythrocyte sedimentation rate (ESR) are advised for all patients suspected of having osteomyelitis. **A CT scan or an MRI scan is indicated for patients suspected of having a retained foreign body.**

Prescribe nonsteroidal anti-inflammatory drugs for analgesia. Instruct the patient to elevate the foot as much as possible in the next 48 hours. Adjunctive treatments such as epsom salts or tepid water soaks may have some benefit, but this has not been proven in clinical trials. Give the patient a wound care sheet and instruct them to return to the Emergency Department if they experience worsening pain, swelling, erythema along the dorsal surface of the foot, or a draining sinus. Patients should be non-weight bearing with crutches for 48 hours at which point they should be reassessed by a Primary Care Physician, Podiatrist, or Orthopedist.

COMPLICATIONS

The most frequently encountered complications of a puncture wound to the foot are cellulitis, soft tissue abscesses, osteomyelitis, foreign body granulomas, tendon lacerations, and nerve injury.¹⁵ Symptoms persisting beyond 24 hours of the injury increase the possibility that complications will develop.^{2-6,8} Late presenters with signs of cellulitis despite appropriate antibiotics may have a retained foreign body.^{2,16} It is estimated that 8% to 15% of all puncture wounds of the foot progress to a cellulitis or a localized abscess. Cellulitis is often due to normal skin flora. Approximately 0.6% to 1.8% of patients develop osteomyelitis within 16 months of the injury.²

Osteomyelitis is a rare complication and is difficult to treat. ***Pseudomonas aeruginosa* is the most common organism isolated.** It is thought that the use of prior prophylactic antibiotics, increased regional humidity from wearing shoes, or the presence of a serous exudate from the wound may facilitate the growth of *Pseudomonas*.^{4,6} The diagnosis of osteomyelitis can be made from clinical features such as a draining sinus visualized to bone or radiographic evidence of disruption of the bony cortex. Consider obtaining a CT scan, a bone scan, or radiolabeled white blood cell scan to make the diagnosis. Treatment involves surgical debridement and/or intravenous antibiotics for 4 to 8 weeks.^{9,10}

SUMMARY

The paucity of clinical trials in this area of Emergency Medicine makes the management of plantar puncture wounds controversial. Simple and small plantar puncture wounds have a low incidence of complications. The presence of a retained foreign body and unknown depths of penetration make puncture wounds vulnerable to complications. A thorough history and physical examination are crucial to stratify patients for risk and to start initial therapy. Basic cleansing and debridement of devitalized tissue along with good follow-up and discharge instructions are the cornerstones of treatment. Tetanus prophylaxis should be reviewed with all patients. Prophylactic antibiotics are discouraged unless the wound is grossly contaminated.

Late presenters often have established wound infections requiring antibiotic treatment and appropriate referrals. Retained foreign bodies are a common cause of infections and require a thorough search. Osteomyelitis is a rare but serious complication. Involving Podiatric or Orthopedic Surgery, as well as using investigations (e.g., CT scan, bone scan, and ESR), can be important adjuncts for the treatment of these wounds. Frequent and timely follow-up remains the current standard of care to avoid infectious complications until further studies of antibiotic prophylaxis and initial puncture wound management can resolve the controversies.

Toe Fracture Management

JoAnna Leuck and Tyler Hedman

INTRODUCTION

Toe fractures are the most common fracture of the foot. They result most commonly from a direct blow (e.g., from an object falling on an unprotected toe) or a “stubbing” injury.^{1,2} The incidence of toe fractures has been estimated at 140 cases per 100,000 people per year, with the first and fifth toes being the most commonly affected.^{1,3} The significance of toe fractures depends greatly upon which digit is affected. Most significant is a fracture of the great toe due to being the main propulsive segment of the forefoot.⁴ Many patients do not present to the Emergency Department as they consider the injury trivial. Those who do present often do so because of severe pain and/or a large subungual hematoma.

Toe fractures are common injuries that rarely require surgical treatment. **The primary goals of treating toe fractures are reestablishing and maintaining alignment, regaining range of motion, preventing complications, and managing pain.** They may be completely and definitively managed in the Emergency Department. Most toe fractures require only a properly placed splint. Between 91% and 97% of toe fractures are nondisplaced or minimally displaced. These fractures often require a closed reduction.^{1,5} An intraarticular fracture with severe displacement of the great toe may require an open reduction and internal fixation to prevent deformity and arthritis in the joint. Complications of toe fractures include damage to the articular cartilage, hypermobility of fracture segments, malposition, and malunion.

ANATOMY AND PATHOPHYSIOLOGY

The foot can be anatomically divided into the forefoot, the midfoot, and the hindfoot (**Figure 220-1**). The forefoot is composed of the metatarsals and their respective phalanges. Sesamoid bones often lie along the plantar surface of the metatarsal heads. The sesamoid bones of the great toe lie in a groove on the plantar surface of the metatarsal head and within the tendon of its respective flexor hallucis brevis muscle belly. Each toe has two pairs of digital nerves that course along the superior and inferior aspects of the digit. The

FIGURE 220-1. The bony anatomy of the foot.

digital artery and vein accompany the nerve. The great toe often receives superficial cutaneous nerves along its dorsal surface.

Anteroposterior and oblique radiographic views will demonstrate most fractures. Lateral views may be necessary to identify phalangeal fractures of the great toe. Obtain the lateral projection with toes 2 through 5 passively dorsiflexed to avoid overlap. An alternative method to achieve adequate radiographic views of the great toe in the lateral projection is to insert dental x-ray film between the first and second toes and direct the x-ray beam laterally.⁶

INDICATIONS

The indications for simple splinting of toe fractures are to relieve pain and allow for healing. The management of closed fractures depends upon the digit involved. Nondisplaced phalangeal fractures of the great toe can be managed with buddy taping to the adjacent normal toe as a splint. Some sources recommend a short leg cast with a toe plate or a short leg walking boot for 2 to 3 weeks for a great toe fracture.⁴ Mildly displaced phalangeal fractures of the great toe can be reduced using local anesthesia, gentle traction, and then placement of buddy tape versus a short leg cast or boot.⁴ Manage nondisplaced phalangeal fractures of toes 2 through 5 with buddy taping. Mildly displaced phalangeal fractures of toes 2 through 5 can be reduced using local anesthesia, gentle traction, and buddy taping. Exact anatomic reduction of toes 2 through 5 is not a concern if the general alignment of the toe is satisfactory.⁷

CONTRAINDICATIONS

Consult an Orthopedic Surgeon or Podiatrist for open fractures, extensive crush injuries to the forefoot, injuries with the potential to progress toward a compartment syndrome, intraarticular fractures, or severely displaced toe fractures. The incidence of arthritis and malunion is quite high with these injuries. Fractures of multiple toes on one foot cannot be treated with buddy taping.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution without epinephrine

- 25 or 27 gauge needle
- 5 mL syringe
- 2×2 gauze squares or a soft corn pad
- Finger trap, optional
- Bunion pad
- Metatarsal bar or wooden tongue depressors
- Permeable tape, ½ inch wide
- Fluoroscopy unit, optional

The use of a fluoroscopy unit, if available, will facilitate an easier and quicker reduction technique. It allows for immediate evaluation of the reduction, multiple reduction attempts without the waiting time associated with serial plain radiography after each reduction attempt, and the reduction to be completed and splinted before the anesthesia wears off.

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Obtain a signed informed consent for the procedure. Obtain plain radiographs or fluoroscopic images to assess the severity of the injury. Place the patient sitting upright so that the affected foot is suspended above the floor to allow adequate space for manipulation and splinting of the toe. An alternative is to place the patient supine with their hip and knee flexed so that the sole of the foot is flat against the gurney. Drain a subungual hematoma (Chapter 127) to relieve the pressure on the nail bed and improve patient comfort.

The use of anesthesia is Emergency Physician and patient dependent. Buddy taping of nondisplaced fractures of toes 1 through 5 or minimally displaced fractures of toes 2 through 5 requires no anesthesia. Consider performing a digital block (Chapter 156) if the patient is significantly tender and a displaced fracture must be reduced. Clean the web spaces of the affected toe of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the web space and surrounding skin. Allow the solution to dry. Arm a 5 mL syringe containing local anesthetic solution (e.g., lidocaine or bupivacaine) without epinephrine with a 25 or 27 gauge needle.

Insert the needle into the dorsal surface of the web space. Aim the needle 45° downward and toward the posterior aspect of the phalanx (**Figure 220-2A**). Advance the needle while injecting 1 to 2 mL of local anesthetic solution. **Do not puncture the plantar surface of the toe.** The local anesthetic solution will easily inject into the areolar tissue of the web space. Withdraw the needle. Shift the needle so that it is aimed along the dorsal surface of the toe (**Figure 220-2B**). Advance the needle while injecting 1 to 2 mL of local anesthetic solution over the dorsal surface. Completely withdraw the needle. Inject local anesthetic solution into the contralateral side of the affected toe in the same way as in the first web space. Allow 5 to 10 minutes for the block to take effect. Reassess the patient to determine whether the block was successful. An additional injection along the plantar surface of the toe may be required to provide total anesthesia, especially of the great toe.

An alternative is to perform a hematoma block (Chapter 155) by injecting local anesthetic solution directly into the fracture site. Clean and prepare the skin. Insert the needle over the fracture site. Advance the needle until it enters the fracture. Aspirate a small amount of blood to confirm that the tip of the needle is properly positioned within the fracture. Inject 2 to 3 mL of local anesthetic solution into the hematoma. Allow 5 to 10 minutes for the local anesthetic to take effect before proceeding.

FIGURE 220-2. Digital block of the toe. **A.** Needle position and direction for infiltration of the lateral surface. **B.** Needle position and direction for infiltration of the dorsal surface.

TECHNIQUES

FRACTURE REDUCTION

Closed reduction can be achieved with the use of the finger trap or straightforward axial traction. Place the anesthetized toe in the finger trap (**Figure 220-3**). Elevate and suspend the foot by the affected toe in the finger trap (**Figure 220-3**). Allow the weight of the leg to slowly distract the fracture site.

Reduce the fracture (**Figure 220-4**). Grasp the forefoot near the base of the affected toe or fractured phalanx with the nondominant index finger and thumb. Grasp the distal aspect of the fractured phalanx with the dominant index finger and thumb. Apply distally directed inline traction with the dominant hand and apply simultaneous countertraction with the nondominant hand to distract the fracture site. Remove the toe from the finger trap. Obtain a radiograph or fluoroscopic image to confirm the reduction. Buddy tape the toe to the adjacent toe as described below.

FIGURE 220-3. Use of the finger trap to aid fracture reduction.

The alternative is to reduce the fracture manually without the use of a finger trap (**Figure 220-4**). Grasp the forefoot near the base of the affected toe or fractured phalanx with the nondominant index finger and thumb. Grasp the distal aspect of the fractured phalanx with the dominant index finger and thumb. Apply distally directed inline traction with the dominant hand and apply simultaneous countertraction with the nondominant hand to distract the fracture site. Reduce the fracture. Obtain a radiograph or fluoroscopic image to confirm the reduction. Buddy tape the toe to the adjacent toe as described below.

BUDDY TAPING

Buddy tape the toe after the reduction (**Figure 220-5**). Place a piece of folded 2×2 gauze or a corn pad between the fractured toe and its neighboring toe (**Figure 220-5A**). The gauze or corn pad will prevent maceration and pressure necrosis of the skin. Tape the toes together (**Figure 220-5B**).

ASSESSMENT

Reassess the toe's perfusion by checking capillary refill time after any attempt at reduction. Obtain a postreduction radiograph or fluoroscopic image to verify proper alignment. Mild to moderate displacement in phalangeal fractures of toes 2 through 5 is quite acceptable if the toes are not rubbing together. Repeat the reduction process as necessary to reduce the fracture. Consult an Orthopedic Surgeon or Podiatrist if the fracture cannot be adequately reduced.

FIGURE 220-4. Manual fracture reduction.

FIGURE 220-5. Buddy taping the fractured toe. **A.** Place gauze or a corn pad between the fractured toe and an adjacent toe. **B.** Tape the toes together.

AFTERCARE

All toe fractures are persistently painful. They require analgesia and splinting for 2 to 3 weeks. Prescribing nonsteroidal anti-inflammatory drugs (NSAIDs) supplemented with narcotic analgesics has been the standard of care. Research may shift future management from the use of NSAIDs as these medications can delay fracture healing.⁸ The patient can apply ice packs for 10 to 15 minutes every 3 hours to help decrease pain and swelling. Provide the patient with a hard-soled shoe, wooden-soled shoe, or Reese orthopedic shoe. It is felt that dorsiflexion of the forefoot in walking causes the most pain in toe fractures.⁵ The use of these shoes, as opposed to the patient's own shoes, minimizes pain with walking.

An alternative to the orthopedic shoe is to place a metatarsal bar for patient comfort.⁹ Use a commercially available unit or make a metatarsal bar by taping wooden tongue depressors together (**Figure 220-6**).⁶ Obtain four tongue depressors and cut one in half (**Figure 220-6A**). Place two tongue depressors side by side (**Figure 220-6B**). Place the third tongue depressor to cover the seam of the adjacent tongue depressors (**Figure 220-6B**). Tape the tongue depressors together to form longitudinal support (**Figure 220-6C**). Apply the cut tongue depressor to form transverse support (**Figure 220-6D**). Tape the transverse support to the longitudinal support (**Figure 220-6E**). Apply the metatarsal bar to the sole of the patient's shoe (**Figure 220-7**). Additional support and pain control can be achieved by immobilizing the foot in a short leg walking cast with a toe plate or a short leg boot for 2 to 3 weeks.⁴⁻⁷ This is true for great toe fractures or if the patient complains of persistent pain.⁴⁻⁷

Instruct the patient to continue weight bearing as tolerated and to elevate the foot above the level of their heart when not walking to minimize swelling. Teach the patient how to reapply the buddy taping splint as it must be changed every 2 to 3 days for up to 6 weeks. Inform the patient that swelling may last up to 3 months, especially with return to activity or wearing of tight-fitting shoes. All patients with great toe fractures should follow up with an Orthopedic Surgeon or Podiatrist within 2 to 7 days for reevaluation. Follow-up in several weeks for all fractures of toes 2 through 5 toe fractures has previously been the standard of care. Recent data showing very low complication rates for simple nondisplaced fractures demonstrate that these can be treated definitively from the Emergency Department. Other than great toe fractures, as previously discussed, the indications for Orthopedic Surgeon or Podiatrist follow-up include intraarticular fractures, phalangeal fractures with gross deformity upon presentation, and fractures that involve the growth plate.⁵

COMPLICATIONS

Long-term sequelae from toe fractures are rare. Persistent angulation at the fracture site with a malunion may result in a "sore area" on the plantar surface of the toe. Refer the patient to an Orthopedic

Surgeon or Podiatrist if such areas remain symptomatic and functionally disabling. A simple surgical procedure may be indicated to correct the problem. Any fractures involving the joint space will result in some degree of arthritis. Warn the patient of this possible complication before they are discharged.

Few complications are associated with the management of toe fractures. Incomplete reduction can result in an angulated toe. Persistent angulation can result in the toe pushing against adjacent toes, skin irritation, and possible skin ulceration. Always place a pad between the toes before buddy taping to prevent irritation, pressure necrosis, ulceration, and maceration of the skin.

FIGURE 220-6. Fabricating a metatarsal bar from tongue depressors. **A.** Lay out four tongue depressors, one of which is cut in half. **B.** Place two tongue depressors side by side. Place the third tongue depressor to cover the seam between the first two. **C.** Tape the tongue depressors together to form the longitudinal support. **D.** Apply the cut tongue depressor to form the transverse support. **E.** Tape the transverse support to the longitudinal support.

FIGURE 220-7. Application of the metatarsal bar to the patient's shoe. **A.** Inferior view. **B.** Lateral view.

SUMMARY

Toe fractures are commonly seen in the Emergency Department. They may cause the patient significant pain and discomfort. Simple conservative management with the use of buddy taping and appropriate footwear helps the fracture heal in 3 to 6 weeks. Open or closed surgical reduction of phalangeal fractures may be required to achieve proper reduction. Intraarticular or severely displaced toe fractures, especially those of the great toe, should be referred to an Orthopedic Surgeon or Podiatrist. Most toe fractures can be satisfactorily and definitively managed by the Emergency Physician with minimal complications.¹

Plantar Wart Management

Kevin O'Rourke

INTRODUCTION

Plantar warts (i.e., verruca pedis) are caused by infection of the epidermal skin layer with the human papillomavirus (HPV). Plantar warts were discussed as far back as the ancient Greeks and Romans. They were subsequently identified as being caused by infectious agents in the late 1800s. HPV, a member of the Papovaviridae family, was identified in 1949 and is composed of double-stranded DNA. The peak incidence of plantar warts occurs in the teenage years.¹ They are estimated to occur in 10% of children and young adults, with a greater prevalence in females. HPV enters the host keratinocyte through an epidermal abrasion with the help of a transiently impaired immune system. It is found in the upper epidermis and results in squamous epithelial cell hyperplasia. Numerous types of HPV exist. Simple plantar warts are mainly due to HPV types 1, 2, 4, 27, or 57.

Two-thirds of untreated common warts in children regress spontaneously within 1 to 2 years.^{1,2} Patients seek treatment despite these high remission rates in part because of their location. Large warts on weight-bearing areas can be painful and disabling. They can be transmitted to adjacent or distant body areas if left untreated. Patients often present with the plantar wart and request its removal. No single therapy has been proven effective at achieving complete remission and there are many different approaches to therapy. Warts typically continue to increase in size and distribution and may become more resistant to treatment over time.³

This chapter summarizes the pathogenesis of plantar warts and three techniques for their removal. The Dermatologist has other treatments they can apply to remove plantar warts.⁴⁻⁶ This includes ablation, the injection of a variety of substances, laser removal, and needling.

ANATOMY AND PATHOPHYSIOLOGY

One must recall the layers of the skin to understand the pathogenesis of the HPV (Figure 221-1). The skin is composed of the epidermis, the dermis, and the subcutaneous tissue or hypodermis. The epidermis on the sole of the foot consists mainly of stratified squamous epithelium. The thickness of the epidermis ranges from 0.05 mm on the dorsal surface of the foot to 1.5 mm on the plantar surface.⁷ HPV replication occurs in the most superficial epidermal layer. The dermis is composed of connective tissue and serves as a scaffold for the skin. The blood vessels, nerves, glands, and hair follicles are in the dermis.

HPV is a DNA virus. It gains access to host cells and uses the host's replicating cell proteins to manufacture viral proteins and DNA. This replication process induces epithelial cell hyperplasia and results in the mound of thickened skin observed in a plantar wart. The HPV remains in the epidermis but spreads laterally from the mound of verrucous tissue into what appears to be normal-looking epidermis. Intracellular HPV can remain in the dormant state as the host's cell-mediated immunity holds it in check. Untreated, solitary, and small to mid-sized warts have a remission rate of approximately 70% in 2 years, with only 20% of the initial lesions persisting in immunocompetent individuals.^{1,2}

INDICATIONS

The task force of the American Academy of Dermatology's Committee on Guidelines of Care has evaluated the indications for treatment of any wart.² They include patient request for therapy, symptomatic warts (e.g., pain, bleeding, itching, or burning), lesions that are disabling or

FIGURE 221-1. The anatomy of the skin.

disfiguring, many or large-sized lesions, to prevent spread to other body areas, and warts in patients who are immunocompromised.

CONTRAINDICATIONS

There are few contraindications to the removal of a plantar wart. **Any lesion whose diagnosis is uncertain requires a biopsy and/or an evaluation by a Dermatologist prior to any ablative removal.** An asymptomatic plantar wart should not be treated in the Emergency Department simply based on its presence. Relative contraindications for cryotherapy include patients who suffer from cold urticaria, cold intolerance, cryofibrinogenemia, cryoglobulinemia, diabetes, or peripheral vascular disease. Patients with diabetes or peripheral vascular disease have poor plantar blood circulation, may take longer to heal, and are at increased risk of developing a subsequent infection. Patients with hepatitis B, inflammatory bowel disease, or active collagen vascular disease may have an exaggerated freeze response and poor wound healing.⁷ Patients taking corticosteroids or who are immunocompromised may have an exaggerated freeze response and poor wound healing.⁷ Renal transplant patients have a higher incidence of warts after transplantation and their immunocompromised state should be kept in mind before doing the procedure.

EQUIPMENT

■ GENERAL SUPPLIES

- Povidone iodine or chlorhexidine solution
- 25 or 27 gauge needle

- 3 mL syringe
- Local anesthetic solution without epinephrine
- EMLA cream
- #15 surgical scalpel blade on a handle or straight razor blade
- Nonsterile gloves
- 4×4 gauze squares
- Pumice stone
- Petroleum-based lubricant (i.e., Vaseline)

■ CRYOTHERAPY

- Liquid nitrogen stored in a Dewar tank
- Handheld, self-contained spray devices (i.e., CRY-AC in 300 or 500 mL canisters)
- Cotton-tipped applicators
- Foam cup
- Otoscope earpiece

■ SALICYLIC ACID THERAPY

- Cotton-tipped applicators
- 15% to 40% salicylic acid ointment in collodion, with optional 20% lactic acid
- Clear nail polish or petroleum-based lubricant
- Occlusive dressing, Band-Aid or Tegaderm

■ DUCT TAPE THERAPY

- Duct tape
- Emery board

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative. Obtain a signed informed consent for the procedure. Mention that the patient might experience a “burning” discomfort with the liquid nitrogen application and a possibility of throbbing pain for up to 24 hours. Consider administering acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) before or after the procedure.

The area of the wart must be clean, dry, and well exposed. Place the patient in a position of comfort. This may be prone, supine, or standing with the ipsilateral knee and leg resting on a chair. Clean the plantar surface of the foot of any dirt and debris. There is no need for sterile preparation or draping of the foot. Position an overhead light so that the beam is focused onto the wart. **Adequate lighting is essential.**

Anesthesia is rarely required for cryotherapy or the application of salicylate acid to plantar warts. Children, nervous adults, or persons with large warts may require anesthesia. One option is to apply EMLA cream to the wart followed by an occlusive dressing for 1 hour prior to the procedure.

Local injection of an anesthetic agent is an alternative. Clean the skin overlying and surrounding the wart site of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Inject a small volume of 1 to 2 mL of a local anesthetic solution to create a wheal under the plantar wart. The editor believes this to be cruel and unusual punishment for the patient. Local infiltration is extremely painful as there are numerous sensory nerve fibers in the sole. The tough and tight skin of the plantar surface quickly comes under tension with the injection of the local anesthetic solution and results in undue discomfort.

Perform a posterior tibial nerve block (Chapter 156) if injection anesthesia is required. The posterior tibial nerve is superficial at the ankle, midway between the medial malleolus and the heel (**Figure 156-40**). It lies between the tendons of the flexor digitorum longus and flexor hallucis longus muscles. It travels with and slightly posterior to the posterior tibial artery. The posterior tibial nerve divides at the inferior border of the calcaneus to form the medial and lateral plantar nerves. The nerves provide motor innervation to the intrinsic foot muscles. The lateral plantar nerve provides sensory innervation to the lateral one-third of the sole and plantar surface of the lateral 1½ toes (**Figure 156-27**). The medial plantar nerve provides sensory innervation to the medial two-thirds of the sole and the plantar surface of the medial 3½ toes (**Figure 156-27**).

Place the patient supine with the ankle supported on a pillow or blanket and the leg externally rotated. Identify by palpation the medial malleolus and the posterior tibial artery by its pulsation. Place a skin wheal of local anesthetic solution at the level of the upper border of the medial malleolus and just posterior to the posterior tibial artery or medial to the Achilles tendon (**Figure 221-2**). Insert a 25 gauge needle through the skin wheal and perpendicular to the skin (**Figure 221-2**). Advance the needle to the tibia or until paresthesias are elicited. If paresthesias are elicited, withdraw the needle 2 mm and allow them to resolve. Inject 3 to 5 mL of local anesthetic solution. If paresthesias are not elicited, infiltrate 5 to 7 mL of local anesthetic solution starting against the posterior tibia as the needle is withdrawn.

FIGURE 221-2. The posterior tibial nerve block. Note the course of the posterior tibial artery (A), the course of the nerve (N), and the needle position.

TECHNIQUES

WART PREPARATION

The plantar wart often has a thicker epidermal layer than the adjacent normal epidermis. Trim the wart to allow easier and more efficient penetration of the liquid nitrogen or salicylic acid (**Figure 221-3**). Use a #15 blade or a straight razor blade to shave the wart's surface. Place a 4×4 gauze square under the patient's foot to catch the shavings. Approach the plantar wart at its base and at a 30° to 45° angle to the skin. Gently move the blade in a smooth sawing motion. Trim the wart to reduce it to a flat structure contiguous with the adjacent normal epidermis. It may take several passes of the blade to trim the wart. Soak the affected foot in lukewarm water for 5 to 10 minutes if the wart is very hard and difficult to trim. **Thoroughly dry the wart and the surrounding skin after the soak. The skin must be dry before the application of liquid nitrogen or salicylic acid.** Proceed with the cryotherapy or salicylic acid treatment as these agents can now easily penetrate through the trimmed plantar wart.

CRYOTHERAPY

Cryotherapy may affect wart clearance by simple necrotic destruction of HPV-infected keratinocytes or possibly by inducing local

FIGURE 221-3. Trimming the wart with a scalpel blade.

inflammation conducive to the development of an effective cell-mediated response. Cure rates for cryotherapy vary widely depending on the treatment regimen. The highest cure rates are achieved when treatment occurs at a frequency of every 2 to 3 weeks.² This technique is not suitable for children under 10 years of age.

Cryotherapy can be achieved using one of two methods. A self-contained liquid nitrogen spray can (e.g., CRY-AC) makes the job very easy (**Figure 221-4A**). Use a spot-freeze technique. Hold the spray tip 1 to 2 cm from the skin surface and tangential to the wart

(**Figure 221-4B**). Gently pull the spray trigger to form a circular “ice field” overlying the wart (**Figure 221-4C**). **Avoid spraying liquid nitrogen onto the normal epidermis.** A spot-freeze of approximately 30 seconds will form a circular ice field of roughly 2 to 3 mm in diameter (**Figure 221-4D**). This corresponds to a depth of freeze of approximately 2 to 3 mm and epidermal temperatures of -5°C to -150°C .⁸ Place an otoscope earpiece over the wart to zone in a more concentrated cryospray for thicker or irregularly shaped plantar warts. This also prevents a “blast” effect and freeze damage to the

surrounding normal tissue. The cure rates approach 97% depending upon the type and number of treatments used.⁷

The lack of liquid nitrogen spray should not impede the use of liquid nitrogen if it is available at your institution. Obtain 5 to 10 mL of liquid nitrogen from the stock tank and place it into a foam cup. Dip a cotton-tipped applicator into the liquid nitrogen. Firmly apply the liquid-nitrogen-soaked cotton-tipped applicator to the plantar wart. Hold the applicator to the wart until a narrow halo of white ice forms around the swab. Larger warts require multiple dips of the cotton-tipped applicator into liquid nitrogen followed by its application onto the wart. **Do not place the cotton-tipped applicator onto the same spot more than once.** Apply the cotton-tipped applicator to cover the entire wart. This technique of touching the plantar wart with a liquid nitrogen-dipped cotton applicator results in a tissue temperature of only -20°C . **It is not as effective as the liquid nitrogen spray at eliminating the plantar wart.**

SALICYLIC ACID THERAPY

Topical therapy with salicylic acid is a safe and effective method. No clear evidence exists to prove that other therapies have an advantage with higher cure rates or fewer adverse effects.⁸ Another guideline lists salicylic acid as the first-line therapy for flat warts on the face, hand, and plantar warts.⁹ Salicylic acid is cheaper, easily available, and can be used by the patient themselves. Salicylic acid ointment is available in a variety of concentrations ranging from 15% to 40%. Salicylic acid ointments can be made in any concentration. The ideal concentration is 40% with or without 20% lactic acid. The lactic acid serves to lower the pH of the ointment and increase the penetration of the salicylic acid into the plantar wart.¹⁰ Topical salicylic acid ointment is recommended over the liquid as it is easy to store and more accurate to apply.

Place a rim of petroleum-based lubricant (e.g., Vaseline) or clear nail polish around the wart (Figure 221-5). This will protect the surrounding normal skin from the effects of the salicylic acid. Allow the nail polish to dry. Apply a coat of salicylic acid ointment up to 2 mm beyond the margins of the plantar wart with a cotton-tipped applicator (Figure 221-6). Completely cover the wart so that the underlying skin does not show through. Apply an occlusive dressing on top of the wart. A clear dressing (e.g., Tegaderm) is useful, thin, allows visualization of the area, and does not affect walking. Daily treatments have an 84% cure rate at 3 months.¹¹

The Mediplast or Duofilm patch of 40% concentration is particularly useful in the management of plantar warts. The plaster

FIGURE 221-5. Application of nail polish around the plantar wart. A clear nail polish was used to circumscribe the region of the plantar wart for this photograph.

FIGURE 221-6. The application of a salicylic acid ointment to cover the plantar wart.

is best applied to the wart and a few millimeters of surrounding skin, taped in place with duct or athletic tape, and kept dry for 48 to 72 hours. The patch is then removed and the wart pared down. This process can be repeated. **The patch must be taped securely in place because it destroys all skin it contacts and must be reapplied if it gets wet.**

Adequate paring of dead skin is an essential component of successful treatment. Paring is performed with a nail file or a pumice stone by the patient in between treatments and/or with a scalpel blade in the Emergency Department immediately before cryotherapy or application of topical agents.

DUCT TAPE THERAPY

Clean and dry the plantar surface of the foot. Apply duct tape to the surface of the foot overlying the wart. Leave the duct tape in place for 6 days before it is removed. Soak the wart in warm water. Instruct the patient to use an emery board to gently remove dead tissue. Allow the wart to remain exposed for about 12 hours. Repeat the duct tape application. Instruct the patient to do this every 6 days for up to 2 months. One study found an 85% cure rate in the duct tape arm versus 60% in the cryotherapy arm.¹²

AFTERCARE

A clear or hemorrhagic blister may form at the site of cryotherapy. The blister is sterile. Leave it intact if it does not interfere with function. It may be punctured with a sterile needle, covered with topical antibiotic ointment, and bandaged if the patient finds the blister a nuisance. Instruct the patient to not pick at the blister. Arrange follow-up in 2 to 3 weeks and after healing has occurred by secondary intention.

Salicylic acid therapy does not produce any pain. The patient's complaints of pain indicate excessive irritation or infection that requires prompt assessment. Teach the patient or their caretaker the application procedure. The application procedure must be performed daily until the wart is gone and for at least a week after that. Be aware that over-the-counter salicylic acid preparations are 15% to 17% in concentration and prescription strength preparations are 30% to 70% in concentration. The most commonly used concentrations for the removal of plantar warts are 40% to 50%.^{8,13}

General instructions include advising the patient to return to the Emergency Department if any signs of an infection develop or there is persistent pain. Mild pain can be managed with acetaminophen

or NSAIDs. Educate the patient on the prevention of future warts and the possibility of recurrence.

COMPLICATIONS

One must understand the normal process of healing after cryotherapy before the complications can be understood.¹⁴ The wound is initially raw and erythematous. It may develop a clear or hemorrhagic bulla. Edema and exudate are expected in the first 24 hours. The use of nonadherent gauze or a bandage is often helpful. Cryotherapy pain lasts no more than 24 hours after the procedure.

The main complications of cryotherapy are pain, delayed bleeding, and infection.¹⁴ Hypertrophic scar formation is rare. Discuss this prior to the procedure if the patient is prone to developing hypertrophic scars. The healing process results in mild skin contractures and depigmentation.⁷ This is less of an issue with the plantar warts compared to lesions on more visible body parts.

Both techniques have the potential to damage normal skin.¹⁴ Do not allow the liquid nitrogen or salicylic acid to extend more than 1 to 2 mm onto the adjacent tissue. Consider using an otoscope cone to prevent blast damage from liquid nitrogen spray. The use of a protective barrier with petrolatum-based lubricant or nail polish will prevent salicylic acid runoff.

There are no known complications with duct tape therapy. This is a cost-effective therapy for patients who are unable to afford a physician. Many people have a roll of duct tape in a drawer at home.

SUMMARY

Plantar warts are extremely common. They can be readily managed in the Emergency Department. Treatment consists of a one-time liquid nitrogen application, daily salicylic acid ointment applications, or weekly duct tape therapy. The key to success is patient education. Patients need to know the entire aftercare plan due to the possible complications and recurrence.

Neuroma Management

Justin Bosley and Eric R. Snoey

INTRODUCTION

Morton's neuroma, also referred to as an interdigital neuroma, is one of the most common painful disorders of the forefoot. It was first described in 1835 by Civinini.^{1,2} It is named after Thomas Morton who presented a case series of patients afflicted with this disorder in 1876.^{1,2} Patients with an established Morton's neuroma are usually cared for by a Podiatrist or an Orthopedist. They may present to the Emergency Department with a previously undiagnosed neuroma or with a painful exacerbation of a previously diagnosed neuroma.

The term neuroma is a misnomer. Histologic investigation does not reveal the typical proliferation of axons found in true neuromas. Instead, there is a fibrosis and thickening of the perineural tissue with corresponding degeneration of the underlying nerve.³ This condition most commonly affects the third plantar common digital nerve located in the third interspace between the third and fourth metatarsal heads. The second interspace may be affected less commonly. It is rare for neuromas to involve the first or fourth interspaces.

Morton's neuroma disproportionately affects women between their fourth and sixth decades.⁴ It is especially common in those who wear high-heeled shoes, poorly fitting shoes, shoes with poor or no padding, or shoes that are narrow at the forefoot. Persons with pronated or pes cavus feet are similarly at risk.⁵ Neuromas do not usually become symptomatic until their transverse diameter reaches more than 5 mm.⁶

ANATOMY AND PATHOPHYSIOLOGY

Neuromas form just proximal to the bifurcation of the plantar common digital nerves (**Figure 222-1**) and below the deep transverse intermetatarsal ligament (**Figure 222-2**).⁷ The deep transverse intermetatarsal ligament connects the metatarsal heads on the plantar aspect of the foot (**Figure 222-2**).⁷ The neuroma is made up of branches from both the medial and lateral plantar nerves (**Figure 222-1**). Most commonly affected is the third interdigital nerve. It is the largest of the interdigital nerves which may explain the increased frequency of neuroma formation in this location.

FIGURE 222-1. Morton's neuroma most commonly occurs in the third intermetatarsal space beneath the transverse metacarpal ligament.

FIGURE 222-2. Anatomy of the forefoot. Cross-section through the distal metatarsals.

Morton and others postulated that the increased mobility of the fourth and fifth metatarsal heads relative to the more fixed medial portion of the foot results in disproportionate trauma to the third interdigital nerve. Mechanical factors combined with the impingement and stretching from a tight transverse intermetatarsal ligament results in repetitive microtrauma. Histologic evaluation reveals perineural fibroma formation consistent with compression-induced trauma.⁴ Injury begins with edema of the endoneurium, followed by fibrosis beneath the perineurium, axonal degeneration, and finally neuronal necrosis.

Some authors believe that a more significant contributor to neuroma formation is enlargement of the interphalangeal component of the intermetatarsophalangeal bursa. This leads to microvascular trauma.⁸ Movements of the bursa result in minor compressive effects on the adjacent digital arteries leading to ischemia of local neural tissue.

The diagnosis of a Morton's neuroma is usually made clinically based upon classic historical features and physical examination findings.^{3,9,10} The pain of a neuroma is initially intermittent, increases in frequency over time, and eventually becomes constant. The patient may complain of pain, burning, electric shocks, or tingling over the involved intermetatarsal space and occasionally the adjacent toes. Attacks typically occur suddenly after a period of walking, running, or standing. Some patients may complain of pain disturbing their sleep.⁸ The involved toes and web space commonly have hyperesthesia or hypoesthesia. Patients often complain of the unilateral feeling of "walking on a lump." Symptoms are relieved by rest and shoe removal.

Physical examination localizes the pain to the involved interspace with minimal involvement of the adjacent metatarsal heads.¹¹ Moderate pressure applied proximally in the affected web space reproduces the pain. A small mass, representing the neuroma, can be palpated in approximately one-third of the cases. **A positive Mulder's sign is diagnostic.**^{10,12} This is a click palpated in the interspace during medial and lateral compression of the metatarsal heads (**Figure 222-3**).

Radiographic imaging may help to confirm the diagnosis of a Morton's neuroma and exclude alternative etiologies.⁹ Plain radiographs will not demonstrate a neuroma but may reveal splaying of the involved toes when the neuroma is especially large or show alternative diagnoses (e.g., stress fractures or arthritis). Ultrasound (US) represents the most efficient and effective imaging modality.^{4,13-15} The US was not shown to be an improvement over the clinical examination.¹⁰ An experienced Emergency Physician may identify hypoechoic neuromas as small as 2.9 mm.¹⁶ Magnetic resonance imaging (MRI) is quite effective at identifying the presence of

FIGURE 222-3. Examination for Mulder's click. The thumb and forefinger of the examiner's dominant hand are used to compress the interdigital space. The nondominant hand then performs medial and lateral compression of the metatarsal heads (arrows). A palpable click is diagnostic while pain alone is suggestive of a neuroma.

a neuroma. The cost and access issues make it a less practical choice in the Emergency Department.³ MRI was shown to be equal to US in identifying the neuroma.¹⁷ Computed tomography (CT) may be useful if an MRI is contraindicated or not available. The sensitivity of CT scanning is less than that of MRI or US.⁴

US evaluation of the foot is best accomplished with a high-frequency linear transducer scanning the region in which the patient identifies as the foci of pain.¹³ The plantar and dorsal placement of the US transducer can be used to evaluate the area for a Morton's neuroma (**Figures 222-4 and 222-5A**). The classical finding involves identifying the fibrillar echogenic nerve coursing into a heterogeneous hypoechoic mass (**Figures 222-6 and 222-7**).¹⁸ **Careful attention should be paid when scanning to minimize artifacts that can falsely suggest abnormal findings. The US appearance of nerves and their surrounding tissues can vary depending on the angle of scanning.** Scanning perpendicular to the target structure can help minimize this issue. Scanning the contralateral foot provides a helpful means of identifying abnormal pathology on the affected side.

INDICATIONS

Injection of the neuroma can provide significant pain relief to the patient and confirm a Morton's neuroma as the etiology of the patient's complaints. Injection is indicated after less invasive methods have failed.¹⁹⁻²³ These include foot elevation and rest, nonsteroidal anti-inflammatory drugs, foot manipulation, arch supports, orthoses, and changing footwear to prevent forefoot compression (i.e., low heels and wide toe boxes). Corticosteroid injections can provide partial or complete relief in up to 80% of patients.^{19,24}

CONTRAINDICATIONS

The primary contraindication to injection of a Morton's neuroma is failure to make a correct initial diagnosis. The differential diagnosis for forefoot pain includes a wide variety of pathologies that may closely mimic the presentation of a neuroma. Alternative diagnoses include tarsal tunnel syndrome, peripheral neuropathy, capsulitis, bursitis, rheumatoid arthritis, foreign bodies, avascular necrosis,

stress fractures, and peripheral vascular insufficiency. A careful history and physical examination with discretionary use of imaging modalities will lead to a correct diagnosis.

Injection therapy may be contraindicated in serious athletes.⁵ The steroid injection may result in fat pad atrophy, degeneration of the volar plate, and degeneration of the collateral ligaments. A discussion of alternative therapies to injection therapy is provided in the “Aftercare” section of this chapter.

EQUIPMENT

- Sterile gloves
- Sterile drapes
- Povidone iodine or chlorhexidine solution
- 3 mL syringe
- 22 or 25 gauge needle
- 0.5% bupivacaine without epinephrine
- Injectable methylprednisolone or triamcinolone
- Sterile bandage
- US machine, optional
- US high-frequency transducer, 5 to 12 MHz
- Sterile US transducer cover
- Sterile US gel

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare of the procedure to the patient and/or their representative. Place the patient supine on a gurney with their hip and knee flexed so that the sole

of the affected foot is flat on the gurney. Identify the neuroma by palpation and/or US (**Figure 222-5A**). Mark the location of the neuroma on the patient’s skin (**Figures 222-5B and 222-5C**). Clean the skin overlying the neuroma of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a sterile field.

Prepare for the procedure. Set up a sterile field on a bedside table. Use aseptic technique to open the needle and 3 mL syringe onto the sterile field. Don sterile gloves. Have an assistant hold the medication bottles upside down while sterilely drawing out the medications. Draw 1 mL of 0.5% bupivacaine without epinephrine and 10 mg of methylprednisolone or triamcinolone into the syringe. Another local anesthetic agent without epinephrine may be used instead of bupivacaine. Long-acting local anesthetic agents are preferred as they provide the patient with longer pain relief after the injection.

Prepare the US transducer if using US with the procedure. Have an assistant apply US gel over the footprint of the transducer. Instruct the assistant to place the gel-coated US transducer in the sterile cover while you hold it. Have the assistant place sterile US gel over the dorsum of the patient’s foot. Reidentify the neuroma (**Figures 222-5A, 222-5B, and 222-5C**).

TECHNIQUE

TRADITIONAL TECHNIQUE FOR A PALPABLE NEUROMA

Instruct the patient to moderately dorsiflex their toes to separate the metatarsal heads. **Use a dorsal approach to the neuroma injection as this is less painful than penetrating the sole with a**

FIGURE 222-8. Traditional technique for injection of the neuroma.

needle.²⁵ Insert the needle perpendicular into the skin overlying the neuroma.

Advance the needle perpendicular to the skin and into the neuroma or adjacent into its fascial plane (**Figure 222-8**). Inject the affected interspace with 1 to 2 mL of the combination long-acting local anesthetic agent and steroid. Remove the needle. Apply pressure to the skin puncture site followed by a bandage.

TRADITIONAL TECHNIQUE FOR A NONPALPABLE NEUROMA

Sometimes the neuroma is not palpable but the physical examination is positive for a neuroma. Insert the needle approximately 1 to 2 cm proximal to the web space. Direct the needle into the fascial space between the deep and superficial transverse metatarsal ligaments. Note that this space is deep to the metatarsal heads on the plantar aspect of the foot (**Figure 222-2**). Inject the affected interspace with 1 to 2 mL of the combination long-acting local anesthetic agent and steroid. Remove the needle. Apply pressure to the skin puncture site followed by a bandage.

ULTRASOUND TECHNIQUE

The use of bedside US by the Emergency Physician has made the diagnosis and procedures more accurate. US guidance may improve the efficacy of steroid injection.²⁶⁻²⁸ Use the US transducer with the sterile cover to identify the neuroma (**Figures 222-5A, 222-5B, and 222-5C**). Hold the US transducer in place to visualize the neuroma on the US machine monitor. Insert the needle (**Figure 222-5D**). Advance the tip of the needle under direct visualization until it is abutting the target structure (**Figure 222-7**). Inject the affected interspace with 1 to 2 mL of the combination long-acting local anesthetic agent and steroid. The injected medication can be seen adjacent to the target structure when performed correctly (**Figures 222-6 and 222-7**).¹⁴ Remove the needle. Apply pressure to the skin puncture site followed by a bandage.

ALTERNATIVE TECHNIQUES

Various types of conservative treatment can be initiated once a Morton's neuroma is diagnosed. Success rates have been reported from 20% to 80% with a combination of injections with other conservative therapy including massage, physical therapy, orthoses, metatarsal pads, shoes with wider toe boxes, and physical therapy.^{21-23,29,30} Orthoses are used to help control abnormal pronation but may be

FIGURE 222-9. Placement of a metatarsal pad.

ineffective in treating a neuroma.³⁰ Metatarsal pads serve to spread the metatarsal heads at the involved interspace and decrease compressive trauma (**Figure 222-9**). The types of physical therapy employed include massage, US, electrical stimulation, and whirlpool immersion. A trial of acetaminophen or nonsteroidal anti-inflammatory drugs may be helpful in the short term.

Studies have described the injection of dilute alcohol into the site of the neuroma using US guidance.³¹⁻³⁵ The effect is to sclerose and harden the perineural tissues. The injection is typically repeated every 1 to 2 weeks for four to seven times with treated patients experiencing a significant reduction in symptoms and neuroma size. Sclerosing agents (e.g., ethanol) injected under US have demonstrated more consistent results when compared to blind landmark-based approaches.³¹⁻³³ The long-term results of alcohol injection does not appear to be effective.³⁶ The neuroma regrows and causes pain.³⁶

Podiatrists and Orthopedic Surgeons may offer more aggressive and definitive therapy when conservative measures fail. Other techniques available include the injection of capsaicin, cryoablation, and radiofrequency ablation.³⁷⁻⁴⁰ Surgical excision using a dorsal approach has success rates of 84% to 93%.⁴¹⁻⁴³ The literature offers increasing support for endoscopic decompression of the deep transverse intermetatarsal ligament and leaving the nerve intact.⁴ The advantage is a shorter recovery time which may make this especially desirable for athletes. No long-term results have been reported but short-term results appear quite promising.⁴ Excision using a carbon dioxide laser may allow for an even shorter recovery.⁸

ASSESSMENT

Allow 10 to 20 minutes for the local anesthetic agent to take full effect. The patient will experience a rapid resolution of symptoms if the injection was successful. The relief of pain confirms that the corticosteroid has been injected into the correct location.

AFTERCARE

Pain may be controlled with the use of acetaminophen or nonsteroidal anti-inflammatory drugs. Instruct the patient to wear flat shoes, shoes with flat and wide toe boxes, and to avoid shoes that elevate the heel more than 1 to 2 cm above the metatarsal heads. The patient should avoid activities that place repeated pressure on the forefoot (e.g., bicycling, jogging, and impact sports). Apply a metatarsal pad to decrease compressive forces on the neuroma. Place the dome of

the pad between the third and fourth metatarsals just posterior to the metatarsal heads (**Figure 222-9**). Cold packs can be applied for 10 to 15 minutes every 3 hours to decrease inflammation and pain. This is helpful after activities that aggravate the patient's symptoms. Refer the patient to a Podiatrist or Orthopedic Surgeon for follow-up, additional injection therapy, orthoses, physical therapy, and possible surgical management.

COMPLICATIONS

Complications associated with neuroma injection are exceedingly rare. They include the introduction of infection, damage to neurovascular structures, local fat pad and skin atrophy from the steroid, skin depigmentation or hyperpigmentation, telangiectasias, and thinning of the skin.^{32,33} Fat pad atrophy on the dorsal foot is primarily a cosmetic issue. Fat pad atrophy on the plantar aspect of the foot can result in painful ambulation and gait disturbances.⁴⁴ Skin changes and fat pad atrophy can be prevented by ensuring the injection is deep and properly placed so that the corticosteroids do not leak into the subcutaneous tissues.⁴⁵ It is common for the pain to recur in days to weeks, even when the injection is successful. Single injections may not totally relieve the patient's symptoms. The patient often requires a series of injections every 1 to 2 weeks to be successful.

SUMMARY

Morton's neuroma is one of the most common causes of forefoot pain. Injection therapy is useful in alleviating the symptoms of a neuroma and in confirming the diagnosis, particularly when aided by US guidance. Arrange Podiatric or Orthopedic follow-up for all patients given this diagnosis. More invasive procedures may be needed for the long-term resolution of symptoms.

Management of Select Podiatric Conditions

JoAnna Leuck, Jacob Hurst, and Anant Patel

INTRODUCTION

Socrates once said “To him whose feet hurt, everything hurts.” Patients with foot pain and deformities are commonly seen in the Emergency Department complaining of compromised mobility. The decreased mobility causes a decreased quality of life. The frequency of these disorders increases with age. This chapter addresses common presentations and procedures for the management of the painful foot. Numerous other podiatric procedures (e.g., local anesthesia, ingrown toenails, plantar warts, puncture wounds, toe fractures, ganglionic cysts, neuromas) are discussed in other chapters of this book.

The foot is divided into the forefoot, midfoot, and hindfoot (**Figure 223-1**).¹⁻³ The forefoot is composed of the five metatarsals and the phalanges. The great toe has two phalanges and each of the remaining toes has three phalanges. The forefoot is important in normal gait. The gait consists of a heel strike, forefoot contact, heel lift, peak forefoot loading with metatarsophalangeal joint extension, and toe lift. The first metatarsal bears a large force during walking and running. The first metatarsal supports the longitudinal arch of the foot. The great toe provides stability during forefoot loading.

The great toe is involved in the biomechanics of walking. The bones of the midfoot and hindfoot are referred collectively as the tarsus. The midfoot comprises the cuboid, cuneiform (i.e., medial, intermediate, and lateral), and navicular bones. The hindfoot is composed of the talus and calcaneus. These bones are stressed during walking and running.

Foot injuries are very common. The chief complaint of foot pain often is followed by the clinical examination and radiologic imaging. A detailed knowledge of imaging anatomy is essential for an accurate diagnosis of an injury and to avoid missing an injury. The radiographic superimposition of the midfoot and hindfoot can make the identification of injuries difficult. These injuries are commonly missed during the clinical examination and subsequent imaging.

MANAGEMENT OF PLANTAR LESIONS

INTRODUCTION

The skin on the sole (i.e., plantar surface) of the foot is the thickest skin on the entire body. It is adapted to protect the internal structures from environmental demands. A 150-lb person has dissipated 60 tons of force with each foot after walking a mile.⁴ Hyperkeratosis (i.e., callosity) occurs when the process of keratinization becomes overactive due to shearing forces and pressure points over bony prominences (**Figure 223-2**). This is a normal protective response as the body attempts to protect the irritated skin. It may be seen on the hands of a laborer or on the plantar surfaces of feet in those who

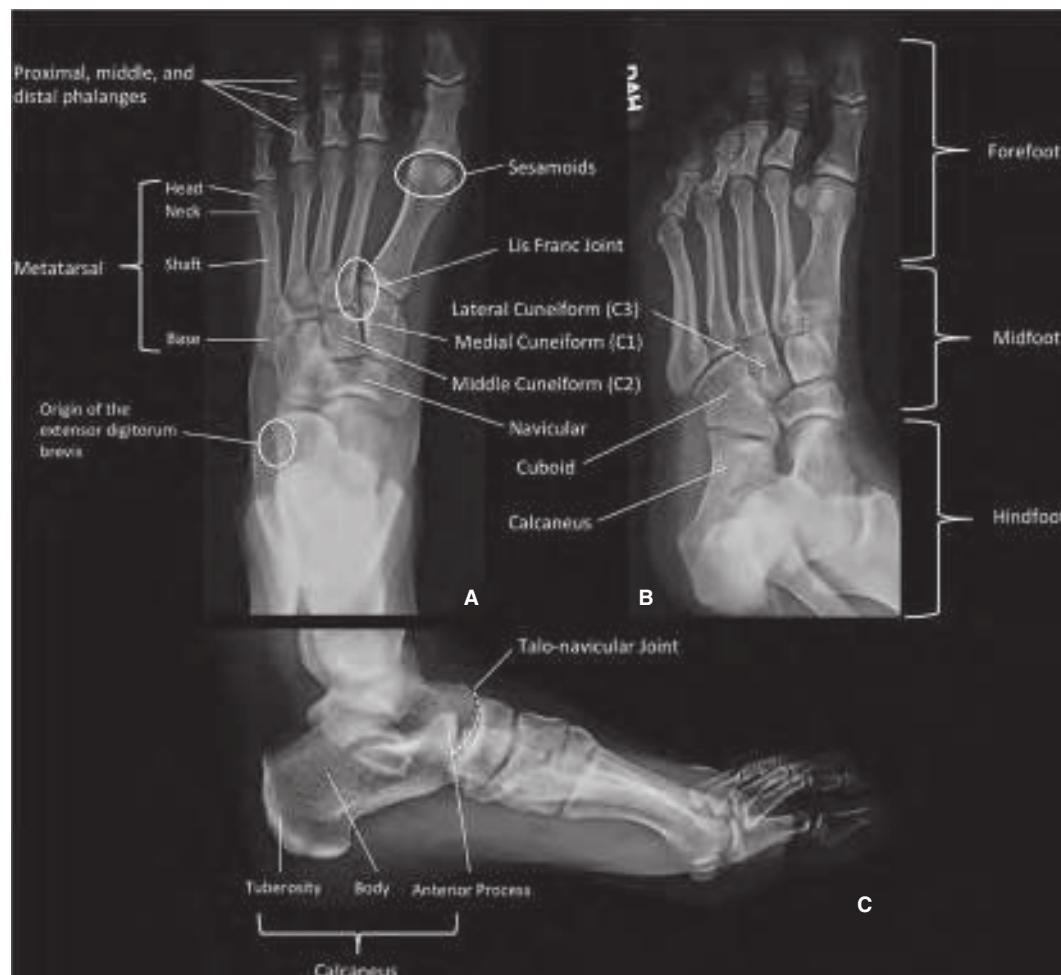

FIGURE 223-1. Foot radiographic anatomy. **A.** Anteroposterior view. **B.** Oblique view. **C.** Lateral view. (Used with permission from reference 1.)

FIGURE 223-2. Calluses of the heel.

walk barefoot. A vicious cycle begins over time. The hyperkeratotic area becomes prominent, increases the pressure in a tight shoe, produces further discomfort, and results in further keratinization.

The ubiquitous verruca virus can invade the plantar skin of the foot and produce a wart or a hyperkeratotic response. It is sometimes difficult to differentiate this condition from other hyperkeratoses (e.g., calluses and corns). Warts may occur at any site on the plantar skin, unlike a pressure- or friction-induced callus or corn. Warts are less likely to occur on the digits and seldom occur on the dorsal skin. **The surface appearance of these conditions may be identical yet their treatment strategies are radically different.** The wart is treated with epidermal eradication (Chapter 221). Other hyperkeratoses are treated with simple paring and rebalancing of the weight-bearing surfaces.

A corn is known as a helomata or a clavus. It represents a well-circumscribed traumatic hyperkeratosis caused by friction or pressure on the skin (**Figure 223-3**). It has a visibly translucent core that presses deeply into the dermis. Corns may be so painful as to be disabling.⁵ A hard corn is known as a heloma durum. It forms

FIGURE 223-3. Numerous painful corns on the toes of a 51 year old female. (Used from Marionette www.commonswikimedia.org.)

primarily on the exposed surfaces of the toes from extrinsic pressure of the footwear.⁶⁻⁹ It is commonly found on the dorsolateral aspect of the fifth toe or the dorsum of the interphalangeal joints of toes 2 to 5.

A soft corn is known as a heloma molle. It is extremely painful and often misdiagnosed as warts or fungal infections. They are macerated and whitish-appearing hard lesions resulting from the corn's absorption of large amounts of sweat. They occur interdigitally, usually in the fourth web space, from wearing tight shoes that press the condyle of a metatarsal against its neighbor. A soft corn will reveal its central "core" if pared.

Another skin lesion that mimics a wart is porokeratosis plantaris discreta. This small cyst-like lesion is a sweat duct filled with a keratin plug. It is located on the plantar surface of the foot. This lesion often goes by the misnomer "seed wart." Their treatment includes curettage or keratolytic agents similar to wart treatment.

Calluses are known as tylomata. They are broad-based, poorly circumscribed, diffuse areas of hyperkeratosis that develop at pressure sites (**Figure 223-2**).⁵ Calluses are usually larger than corns, do not have a central core, and may or may not be painful. A large area of hyperkeratosis that occurs in combination with a centrally located plug of keratin is called an intractable plantar keratosis (IPK). These lesions usually require podiatric evaluation for debridement, protective padding, and rebalancing of the weight-bearing surfaces with orthotics.

Hammertoes are a contracture of the toes from of a muscle imbalance between the tendons on the top and the bottom of the toe (**Figure 223-4**). Hammertoes can be flexible or rigid. Hammertoes occur when the intrinsic muscles of the foot lose their stabilizing effect on the interphalangeal joints allowing the extrinsic muscles of the leg to overpower and flex the interphalangeal joints. This deformity may be associated with the formation of painful hyperkeratotic lesions. The patients develop corns on the top of the toe from rubbing and a callous on the ball of the foot from the toe pressing downward (**Figure 223-5**). The callous becomes prominent from the pressure of the bone. These lesions may be overlying or adjacent to any or all the interphalangeal joints or on the distal tip of the digit.¹⁰

The most common cause of hammertoes are tight shoes. The shoe forces a toe to stay bent, the muscles tighten, and the tendons contract. Other causes of hammertoes are congenital abnormalities, contractures (e.g., bedridden or cerebral palsy), joint diseases (e.g., rheumatoid arthritis), nerve injury, peripheral neuropathy, peripheral vascular disease, spinal cord injury, and stroke. Treatment of a

FIGURE 223-4. Hammertoes. (Photo courtesy of RoseMary Mabro, DPM.)

FIGURE 223-5. Hammertoes can cause calluses and corns. The arrows represent some of the pressure points. (Used with permission from www.thion-medical.com.)

hammertoe is multifactorial. Instruct the patient to wear shoes with a roomy toe box to allow the toes to function without excessive pressure. Treat all corns. Use padding to relieve pressure from the toe. Surgery is an option if conservative treatment is unsuccessful.

The first step in treating a patient with a plantar skin lesion is to differentiate a wart (i.e., verruca) from a plantar hyperkeratosis. Warts and plantar corns are best distinguished by paring the outer layer of epidermis with a sharp scalpel blade. Warts may or may not be localized under a bony prominence (**Figure 223-6**). Apply alcohol to the plantar lesion to enhance the skin lines. **The skin lines of a hyperkeratosis pass through the lesion whereas those from a wart pass around the lesion. End arteries are visible when a wart is pared.** These appear as multiple black dots that hurt and bleed if cut (**Figure 223-6**). Paring the hyperkeratotic lesion reveals only yellowish, translucent, firm keratin, even after many shaves. **A firm keratin core is a corn and not a wart.** The patient's pain response to pressure on the lesion may help in differentiating a wart from a corn. Pain is elicited with direct pressure on the hyperkeratotic lesion. Squeezing the wart side to side with a similar force elicits maximal pain.

INDICATIONS

Perform paring to provide temporary relief of pain associated with corns and calluses. **Make the patient aware that paring is not a permanent treatment. The first step in treatment is to suggest a better-fitting shoe.** Identify the lesion type by shaving the outer layers of keratinized epidermis. Examine the shaved surface looking

FIGURE 223-6. Plantar wart on the underside of the great toe. (Used from Dewdude www.commonswiki.org.)

for the identifying characteristics of a wart versus a corn or callus. Trimming the callused hyperkeratotic surface will provide temporary relief from the discomfort of a corn, a callus, and even a wart. Definitive treatment of a wart or porokeratosis requires curettage, acid, freezing, or referral to a Podiatrist. Perform a more definitive shaving if a corn or callus is identified.

CONTRAINDICATIONS

Severe peripheral vascular disease, impaired wound healing, and overlying cellulitis are contraindications to shaving a plantar lesion. A variety of neoplasms may appear as a callused plantar lesion. If there is any suspicion that the plantar lesion is not a simple callus or corn, do not shave the lesions and refer to a foot specialist. **Biopsy is mandatory if there is any question about the nature of the lesion.**⁵

EQUIPMENT

- #10 or #15 surgical scalpel blade on a handle
- Isopropyl alcohol swabs
- 18 gauge needle
- 25 or 27 gauge needle
- Local anesthetic solution without epinephrine
- Cotton ball or 2×2 gauze square
- Tape, 1 inch wide
- Lamb's wool
- Aperture pads

Podiatrists and Orthopedic Surgeons have specialized equipment to debride warts and hyperkeratotic lesions. This includes curettes, mini-blades, chisel blades, and tissue nippers. This equipment is not commonly available in Emergency Departments, clinics, or offices. The techniques described below use commonly available equipment to manage foot lesions.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent to perform the procedure. Soak the foot in warm water for 10 to 15 minutes. Place the patient supine or prone on a gurney. Heel lesions are often best

FIGURE 223-7. Technique for using a scalpel blade in the paring of a hyperkeratotic lesion (curved arrow).

addressed with the patient in the prone position. Sit on a stool so that the lesion is at eye level. Visualize the hyperkeratotic lesion under a bright light. Anesthesia is usually not required. Consider the use of a posterior tibial nerve block (Chapter 156) if the patient is significantly sensitive.

TECHNIQUES

Support the foot to be debrided with the nondominant hand. Wipe the hyperkeratotic area with an alcohol swab. Grasp the skin surrounding the lesion. Place the index finger of the nondominant hand above the hyperkeratotic area and the thumb below it (**Figure 223-7**). Grasp a #10 or #15 scalpel blade on a handle with the dominant hand. Rest the base of the dominant hand against the patient's foot. This allows a measure of safety for both the Emergency Physician and the patient. All materials move in mass with the patient if they move. Place the scalpel blade almost parallel to the lesion (**Figure 223-7**). Remove superficial amounts of the hyperkeratotic lesion using a semicircular slicing motion.¹¹ Continue this process of debriding repeatedly until healthy pink tissue is noted.¹¹ **A central core, if uncovered during the debridement, must be removed to relieve the patient's symptoms.** Insert the tip of the scalpel blade into the core. Carefully and slowly twist the scalpel blade in a circular motion to remove the core. **Avoid injury to the underlying and adjacent healthy tissue.** Treat the common corn with periodic debridement.

Adjunctive therapy includes felt corn pads with a central aperture or a horseshoe to relieve pain and disperse pressure at bony prominences to the surrounding skin (**Figure 223-8**). Place pads under the metatarsals for protection and pressure dispersal from any or all the metatarsal heads. Tape the pads to secure them to the skin.

The macerated soft corn is frequently misdiagnosed on visual inspection as an interdigital fungal infection or wart. Superficial debridement will aid in the diagnosis. Perform a digital or metatarsal block using local anesthetic solution without epinephrine.¹² The digital arteries are end arteries and local anesthetics containing epinephrine can theoretically induce digital ischemia. Pare the hyperkeratotic lesion with a #10 scalpel blade to provide pain relief and a diagnosis.

The toes must be separated while the lesion is healing. Place a cotton ball or a small gauze square between the toes, either distal or proximal to the lesion. Tape the dressing in place. **Never circumscribe the digit with tape due to the risk of circulatory impairment from constriction.** Apply lamb's wool around the affected digit. The advantage of lamb's wool is that tape is avoided and the patient can

FIGURE 223-8. The use of self-adherent aperture pads on the dorsal surface to relieve pressure from a pared hyperkeratotic lesion overlying a bony prominence. Pads are further secured to the skin with tape.

change the dressing daily. A foam interdigital cushion is a good choice for pressure dispersion and can be applied later.

AFTERCARE

The patient can expect 6 to 8 weeks of pain relief after a corn or callus is pared. The procedure may be repeated after this period. Patients must realize that hyperkeratotic lesions are a result of lifestyle choices (e.g., wearing constricting, improperly fitted, and/or high-heeled shoes).¹³ Refer the patient to a Podiatrist if conservative therapy fails.

Provide all patients with verbal and written instructions regarding the signs of infection and lifestyle modification. This includes immediate return to the Emergency Department for increasing pain, progressive swelling, redness, tenderness, and warmth. Follow-up treatment consists of frequent trimming of the keratotic lesion. Consider using shock-absorbing inserts. Metatarsal pads are an excellent choice for submetatarsal pressure dispersion and the protection of pared calluses (**Figure 223-9**). Recommend lifestyle modification

FIGURE 223-9. Examples of self-adherent commercially available padding. **A.** The $\frac{1}{8}$ inch horseshoe digital corn pad. **B.** The $\frac{1}{4}$ inch interdigital soft corn pad. **C.** The $\frac{1}{4}$ inch bunion shield. **D.** The $\frac{1}{4}$ inch submetatarsal pad.

and the use of appropriate footwear. Home care of the macerated corn includes daily astringent soaks with boric acid solution and a topical antibiotic applied with dressing changes.

PADDING

Padding offers temporary and immediate relief for many patients with foot pain associated with bursitis, fasciitis, and tendonitis. Padding relieves pressure around bony prominences by dispersing it to the surrounding skin. The type of pad and its placement depend on the underlying problem (**Figure 223-9**). Many commercial pads are available in felt, gels, and silicone. They are useful for the management of hyperkeratosis secondary to hammer toes, corns, and calluses. The following section discusses the use of padding for common forefoot and hindfoot disorders.

BUNIONS AND BUNIONETTE DEFORMITIES

The bunion affects the first metatarsal head and is known as hallux abducto valgus.¹⁴ The bunionette affects the fifth metatarsal head and is known as the tailor's bunion, as tailors often sit in a cross-leg position with pressure on the lateral foot leading to this lesion. Deformities are identified as painful prominent metatarsal heads and surrounding soft tissues (**Figures 223-10 and 223-11**). Common causes of the bunion and bunionette deformities are complex and multifactorial. These include anatomic and physiologic abnormalities, hereditary conditions, and extrinsic footwear elements.^{14,15} Biomechanical abnormalities lead to dysfunction of the metatarsophalangeal (MTP) joint.

The bunion deformity consists of lateral deviation of the great toe and medial deviation of the first metatarsal (**Figures 223-10**

FIGURE 223-11. The bunion and bunionette deformity. The dotted lines represent the normal metatarsal positions.

and 223-11). The bunionette deformity is a bunion on the lateral aspect of the foot overlying the fifth metatarsal head. The fifth digit is medially deviated with lateral deviation of the fifth metatarsal (**Figure 223-11**). Pain results from shoes causing pressure against the bony deformity and the surrounding soft tissues. This can result in subsequent pressure hyperkeratosis. Clinical examination reveals pain upon palpation along the border of the metatarsal head.

The differential diagnosis of a bunion includes bursitis of the first MTP joint, which commonly occurs over the medial bunion bump.¹⁶ Consider other conditions (e.g., infectious and inflammatory diseases). Associated foot complaints may include lesser metatarsalgia, intermetatarsal neuroma, hammertoes, corns, and calluses.

TREATMENT

The initial treatment consists of removing the offending footwear. Shoes with a spacious toe box minimize pressure against inflamed soft tissues and bony prominences. Carefully pare any hyperkeratotic lesions while avoiding injury to surrounding healthy tissue. Padding and accommodative shields help to disperse pressure and may be beneficial. Precut bunion shields are available (e.g., felt, gels, plastic, or silicone) or may be fashioned from 1 cm thick felt (**Figure 223-12**). Prescribe nonsteroidal anti-inflammatory drugs (NSAIDs) for analgesia. Refer the patient to a Podiatrist or

FIGURE 223-10. A bunion. (Used from Lamiot, www.commonswikimedia.org.)

FIGURE 223-12. The application of a bunion shield.

Orthopedic Surgeon when conservative measures fail.¹⁴ Surgical techniques can be used to correct the underlying bony deformity.

A painful bursa overlying the medial aspect of the first MTP joint is common. Local aspiration of bursal fluid followed by the injection of a local anesthetic agent and a short-acting steroid may relieve pain and decrease the size of the bursa. Clean the skin overlying the bursa of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry. Aspirate the bursa fluid with a 22 gauge needle on a 3 to 5 mL syringe. Inject the bursa with a mixture containing 0.5 mL of local anesthetic solution and 4 mg of dexamethasone.

METATARSALGIA

Metatarsalgia is a general term used to describe a diffusely painful area directly beneath the metatarsal heads (**Figure 223-13**).¹⁷ The patient usually complains of forefoot pain that is insidious in onset with walking, worsens throughout the day, and is relieved with rest. The pathophysiology of metatarsalgia is complex. A common denominator is weight transfer from the first ray during ambulation to the lesser metatarsals. This may promote a bursitis, tendonitis, tenosynovitis, and capsulitis of the lesser MTP joints. The patient can usually point to the painful spot. The second metatarsal head is most commonly involved followed by the third and fourth metatarsal heads.

The clinical diagnosis can be made with direct palpation of each individual metatarsal head. Repetitive force induces a capsulitis or metatarsalgia beneath the metatarsal head that may progress to a stress fracture of the metatarsal. Radiographs may be negative initially with stress fractures. Repeat the radiographs in 2 to 4 weeks. A hyperkeratotic lesion may be associated with this syndrome. It can be located either directly beneath a metatarsal head or diffusely under the metatarsal heads. Paring of the lesion is important for the diagnosis and treatment. Sufficient debridement may provide immediate pain relief in the Emergency Department.

TREATMENT

All hyperkeratotic lesions require debridement for the diagnosis and treatment. Pad the lesion to disperse pressure to the surrounding tissues. Place a 1 cm thick pad beneath an inner sole under the first metatarsal for discrete pain just beneath the second metatarsal head

FIGURE 223-13. Metatarsalgia. (Used with permission from reference 17.)

FIGURE 223-14. A ¼ inch-thick felt pad placed beneath the first metatarsal to redistribute weight and to protect the second metatarsal.

or second proximal phalangeal shaft (**Figure 223-14**). This helps to redistribute the weight-bearing surface and protect the second metatarsal. NSAIDs may provide analgesia. Instruct the patient to wear a well-cushioned good-quality athletic or walking shoe. Arrange follow-up with a Podiatrist or Orthopedic Surgeon to address the underlying reason for the hyperkeratotic reaction.

SESAMOIDITIS

Two sesamoid bones lie beneath the first metatarsal. Their structure and function are similar to those of the patella. The clinical examination reveals pain with palpation beneath the sesamoid bones. This may develop into the more painful conditions of chondromalacia, osteoarthritis, and stress fractures. Radiography can be important in the initial evaluation of the pain in the sesamoid area.¹⁸ The radiographs may be normal, may demonstrate sclerosis, or may demonstrate fragmentation of the involved sesamoid. Radiographic evaluation includes the anteroposterior and lateral radiographs. A sesamoid view can be ordered as an oblique coronal radiograph and allows direct imaging of the joint without osseous overlap.^{18,19} Initial radiographs may be negative.¹⁸ Serial radiographs taken 2 to 4 weeks later may reveal a fracture.

TREATMENT

Nonsurgical treatment that aims at reducing the load under the sesamoids is preferred for sesamoid problems. This includes restriction of activities, modification of footwear, and a moulded orthosis with metatarsal pads.²⁰ Pare any hyperkeratotic lesions. Instruct the patient to wear a well-cushioned good-quality athletic or walking shoe. Apply padding with a central aperture cut out beneath the sesamoid bones to help disperse pressure to the surrounding skin and away from the sesamoid bones. NSAIDs will provide analgesia. Arrange follow-up with a Podiatrist or Orthopedic Surgeon if the patient experiences persistent symptoms.

HEEL PAIN SYNDROMES

The painful heel is a common complaint of the middle-aged and elderly.²¹ An in-depth discussion on the myriad of etiologies for heel pain is beyond the scope of this chapter. Patients most often have no associated disease other than obesity. Consider screening young

men for ankylosing spondylitis or reactive arthritis. Most cases respond to modification of physical activities, the use of NSAIDs, injection of local anesthetic agents and steroids, and the use of specially designed insoles.²¹ The use of heel padding as adjunctive therapy is addressed later.

HEEL SPUR SYNDROME

The process of spur formation is termed heel spur syndrome.^{22,23} The etiology is presumed to be chronic traction on the plantar fascia and intrinsic muscles. This results in repeated microtrauma along the medial calcaneal tuberosity, periostitis, and calcification. The patient complains of heel pain progressing over months. Palpation reproduces the pain along the medial border of the calcaneus. Radiographs reveal the spur emanating from the calcaneal tuberosity (**Figures 223-15 and 223-16**). **Absence of a spur suggests plantar fasciitis as the etiology of the pain.**

EQUIPMENT

- Povidone iodine solution
- 3 mL syringe
- 25 gauge needle, 1¼ inch long
- Ethyl chloride spray
- Local anesthetic solution without epinephrine, lidocaine or bupivacaine
- Dexamethasone
- Felt pad, 1 cm thick
- Tape, 2 inches wide

TREATMENT

Treatment is aimed at conservative measures. NSAIDs will provide analgesia. Padding can temporarily relieve heel pain by reducing central pressure on the more painful part of the heel. Apply a 1 cm thick felt pad or high-grade foam rubber pad cut in the form of a horseshoe directly to the affected heel (**Figure 223-17**). Secure the pad in place with two or three strips of 2 inch wide tape. Instruct the patient to wear the pad for 1 to 3 days. Remove the pad if it becomes wet to avoid skin maceration.

FIGURE 223-15. Lateral hindfoot radiograph demonstrating a heel spur. (Used from Lucien Monfils, www.commonswikimedia.org.)

FIGURE 223-16. Sites of potential heel pain.

The patient's shoes may be modified to help provide pain relief. Place a self-adherent sponge pad into the heel of the shoe to decrease pressure on the calcaneus. Have a cobbler place a cut-out into the heel of the patient's shoe if the patient still experiences pain (**Figure 223-18**). Place a self-adherent sponge pad over the cut-out before the patient wears the shoe.

Injection of local anesthetic solution and corticosteroids is controversial as a treatment in the Emergency Department for heel spur syndrome. **This is due to the risks and complications (i.e., infection, increased pain, and fat pad atrophy).** Treatment with injection of any type is often reserved for a Podiatrist if conservative treatment fails.²⁴

Injection of local anesthetic solution and corticosteroids is useful in reducing acute inflammation. Mix 1 mL of 1% lidocaine hydrochloride, 1 mL of 0.5% bupivacaine hydrochloride, and 0.8 to 1.0 mg of dexamethasone in a 3 mL syringe. Thoroughly mix the contents of the syringe together. Clean the skin overlying the medial border of the calcaneus of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Spray ethyl chloride to anesthetize the skin. Insert a 25 gauge perpendicular to the skin and at the level of the heel spur. Advance the needle in a dart like motion. Infiltrate the local anesthetic-steroid mixture along the medial calcaneal tubercle and the central plantar calcaneus beneath the spur

FIGURE 223-17. Relief of heel pain from a heel spur. A ¼ inch thick pad is cut in the form of a horseshoe and applied directly to the affected heel.

FIGURE 223-18. Shoe modification to relieve heel spur pain.

fascia junction. **Avoid infiltration into the plantar fat pad as this area is extremely sensitive and the steroid can result in fat pad atrophy.** The injection procedure can be repeated in 2 to 4 weeks. Refer the patient to a Podiatrist or Orthopedic Surgeon for persistent symptoms despite steroid injection or for an anatomically supinated or pronated foot.

PLANTAR FASCIITIS

Plantar fasciitis is one of the most common causes of heel pain.^{22,25,26} It is an overuse syndrome like the heel spur syndrome. Excessive traction on the plantar fascia results in localized inflammation and acute pain at its origin on the calcaneus (**Figure 223-19**).²⁵ The inflammation may eventually result in the formation of a heel spur. The pain can progress distally along the fascial course in the chronic form.

The patient generally describes an insidious onset of unilateral heel pain that is characteristically worst first thing in the morning and eases after the first few steps. Plantar fasciitis is common in obese patients and can be caused by the chronic wearing of high-heeled shoes. Women in the 40 to 60 year age group are afflicted more than men. **Clinical examination reveals pain upon palpation along the plantar fascia in the midfoot but not over the area of a heel spur if present.**

Radiographs are generally not helpful at the initial presentation but rather 4 to 6 weeks after the onset if the symptoms persist.

Radiographs will often confirm the presence of a heel spur that may or may not be involved in plantar fasciitis. One study demonstrated that 46% of patients with plantar fasciitis had no spur and 50% of patients who had bilateral spurs had pain in only one heel.²⁷

TREATMENT

Treatment is aimed at conservative measures.^{26,28} NSAIDs will provide analgesia. Instruct the patient to obtain well-fitted and cushioned footwear that supports the medial longitudinal arch, supports the plantar fascial band, and has good heel shock-absorbing qualities. Demonstrate a regimen of active stretching of the medial fascial band (**Figure 223-20A**). It is important to perform this daily. Stand facing a wall and approximately 2 to 3 ft from the wall. Lean forward and place both palms on the wall. Keep both heels firmly pressed on the ground. The stretch should be felt in the Achilles tendon and longitudinal arch. Dynamic stretches such as rolling the foot arch over a 15-oz size can or a tennis ball are also useful.^{28,29} Instruct the patient to stretch three times a day for 3 to 5 minutes.

The use of padding can provide relief for some patients. Place medial longitudinal pads to unload the anteromedial aspect of the heel and support the medial longitudinal arch (**Figure 223-20B**). Make the pad from 0.2 inch thick felt and fashion it to fit the patient's longitudinal arch. Secure the pad in place with two or three strips of 2 inch wide tape. Instruct the patient to wear the pad for 1 to 3 days. Remove the pad if it becomes wet to avoid skin maceration. Numerous commercial pads are available over-the-counter and through a Podiatrist.

Night splints can be helpful in the treatment of plantar fasciitis. They are designed to keep the patient's ankle in a neutral position. A night dorsiflexion splint allows passive stretching of the calf and the plantar fascia. It potentially allows any healing to occur while the plantar fascia is in an elongated position and creates less tension with the first step in the morning. A night splint can be made from plaster, fiberglass, casting material, or a prefabricated commercially produced plastic brace.^{28,29}

Injection of corticosteroids and local anesthetic will relieve any pain refractory to conservative treatment. Injections are relatively invasive and carry a risk of complications (e.g., fat pad atrophy, osteomyelitis of the calcaneus, and iatrogenic rupture of the plantar fascia).³⁰ Limited evidence supports the use of corticosteroid injections to manage plantar fasciitis. Results of a Cochrane review showed that corticosteroid injections improved plantar fasciitis symptoms at 1 month but not at 6 months when compared with control groups.³¹

Prepare the skin and the injection solution as described with the heel spur syndrome. Inject the solution deep into the plantar fascia (**Figures 223-20C and 223-21**). Use of a careful injection technique, use of an aseptic technique, avoidance of impact activities for

FIGURE 223-19. The mechanism of plantar fasciitis. **A.** Normal anatomic relationships. **B.** Traction on the tendon elevates the periosteum from the calcaneus and promotes the invasion of inflammatory tissue. **C.** The inflammatory tissue and periosteal elevation can result in the formation of a heel spur.

FIGURE 223-20. The treatment of plantar fasciitis. **A.** Active stretching of the medial fascial band. **B.** Placement of a medial longitudinal arch pad. **C.** Injection therapy.

10 days after injection, and ultrasound-guided injection may minimize these risks.^{32,33}

The injection procedure can be repeated in 2 to 4 weeks if required. **Do not inject more than two to three times into the plantar fascia. Multiple injections can lead to rupture of the plantar fascia. Avoid injection into the plantar fat pad.** This area is extremely sensitive. Steroids injected into the fat pad can result in

atrophy and loss of the intrinsic shock-absorbing qualities. Apply a medial longitudinal pad as described above. Relief from a combination treatment may last 6 to 8 weeks. Refer the patient to a Podiatrist or Orthopedic Surgeon for persistent symptoms greater than several months and if conservative therapy fails. No evidence strongly supports the effectiveness of any treatment for plantar fasciitis and most patients improve without specific therapy or by using conservative measures.³¹

RETROCALCANEAL BURSITIS

Retrocalcaneal bursitis is a painful condition. It results from inflammation of one or both bursae at the Achilles tendon insertion on the calcaneus (**Figure 223-16**).²² The pain in the posterior heel is insidious in onset. It is aggravated by increased activity and shoes with tight heel counterpoints. Palpate the bursae. Place the patient's foot in plantarflexion to relax the Achilles tendon. Squeeze the anterior part of the tendon just proximal to its bony insertion site in the depression above the calcaneus. Tenderness elicited with a squeezing force applied anterior to the Achilles tendon suggests inflammation of the anterior, retrocalcaneal, or subtendinous bursae. Always exclude the possibility of a systemic inflammatory disease when bilateral. There is an association of retrocalcaneal bursitis with rheumatoid arthritis and is seen in up to 10% of patients.³⁴ Tenderness elicited with pressure on the posterior surface of the Achilles tendon insertion site suggests inflammation of the posterior or subcutaneous calcaneal bursa. Erythema and swelling may be evident at the lateral borders of the Achilles tendon.

TREATMENT

Treatment is conservative and mirrors the treatment for heel spurs. NSAIDs are recommended. Steroid injections are controversial. Many studies have found that the use of injectable steroids is contraindicated as it may lead to tendon rupture. A one-time steroid injection directly into the retrocalcaneal bursa is sometimes helpful in refractory cases of retrocalcaneal bursitis.^{34,35} **Extreme care must be taken to not inject any steroid solution into the tendon. Never perform more than one or two injections. This reduces the risk of tendon atrophy or rupture.** Occasionally bursal fluid is aspirated before the injection of the corticosteroid.³⁴ Apply a horseshoe-shaped heel pad made from 0.25 inch thick felt or foam rubber to the affected heel.

CALCANEAL APOPHYSITIS (SEVER'S DISEASE)

This condition is a common cause of heel pain in skeletally immature patients, particularly in 8 to 14 year old active males.^{22,36-39} It results from excessive traction and microtrauma on the calcaneal apophysis by the Achilles tendon. This typically occurs before or during a growth spurt and shortly after the beginning of a new season or new sport, especially during running and jumping. Clinical examination reveals tenderness at the Achilles tendon insertion site on the posterior calcaneus. Radiographs may reveal an elevated apophysis with scleritis and fragmentation (Figure 223-22).⁴⁰

A

B

TREATMENT

Treatment is aimed at conservative measures.^{41,42} Rest, NSAIDs, and heel lifts fashioned like the pads for heel spurs are recommended. Instruct the patient to perform Achilles tendon stretching exercises three times a day for 3 to 5 minutes (Figure 223-20A). **Steroid injections are not recommended.** Preventative and proactive measures include education of coaches, education of parents, and well-fitted supportive cushioned athletic footwear worn by an active adolescent during activities.⁴³

ACHILLES TENDINITIS

Repeated trauma to the Achilles tendon from faulty footwear, faulty landing techniques, hard landings, or the use of fluoroquinolone antibiotics can lead to inflammation of the tendon and its sheath due to prolonged friction.²² Patients complain of pain with prolonged standing and with climbing stairs that is relieved with rest. Clinical examination reveals erythema and localized pain upon palpation just proximal to the Achilles tendon insertion site on the calcaneus. (Figure 223-23).

TREATMENT

There is no consensus on the best form of treatment for Achilles tendinitis.⁴⁴⁻⁴⁶ An array of nonsurgical interventions (e.g., NSAIDs,

FIGURE 223-23. Erythema and thickening of the left Achilles tendon demonstrating tendinitis. (Used with permission from Knoop KJ, Stack LB, Storrow AB, Thurman RJ (eds): *The Atlas of Emergency Medicine*, 4th ed. McGraw-Hill; 2016. Photo contributor: Kevin J. Knoop, MD, MS.)

rest, stretching and strengthening exercises, heel lifts, and other orthotic devices) are commonly applied. Surgery is often considered for refractory cases.⁴⁴ **Steroid injections of the Achilles tendon are absolutely contraindicated.**⁴⁷ Inform the patient regarding shoe modifications (e.g., cutting out the heel counter point [Figure 223-18] or recommending an open-backed shoe). Apply a 0.25 inch thick felt pad fashioned to fit the heel or a commercial cushioned heel lift as appropriate adjunctive therapy. Refer the patient to a Podiatrist or Orthopedic Surgeon for recalcitrant or severe cases.

ACHILLES TENDON RUPTURE

Achilles tendon rupture is one of the most common tendon failures affecting the lower extremity. It occurs primarily in middle-aged adults who participate in occasional athletic activities. Most of Achilles tendon ruptures occur in the serious athlete during competition or in the relatively sedentary former athlete during demonstrations of former skills on the basketball or volleyball court. Rupture of the Achilles tendon involves a significant force (e.g., push-off), a forceful drive, a direct blow, or landing in sudden dorsiflexion with the foot plantarflexed and extended.²² Rupture of the Achilles tendon can occur at its attachment to the calcaneus, along the tendon, or more commonly at the musculotendinous junction.

Patients typically report a history of sudden pain associated with an audible snap and difficulty tiptoeing or climbing stairs. Clinical findings include a positive Thompson squeeze test (Figure 223-24),

FIGURE 223-24. The Thompson test. **A.** Squeezing the calf with an intact Achilles tendon causes plantarflexion of the foot. **B.** Squeezing the calf with a ruptured Achilles tendon causes no plantarflexion of the foot. (Used with permission from Sherman SC: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

FIGURE 223-25. Achilles tendon rupture of the right foot. Note the edema and lack of plantarflexion. (Used with permission from Sherman SC: *Simon's Emergency Orthopedics*, 7th ed. New York: McGraw-Hill; 2014.)

a positive heel resistance test (i.e., easy dorsiflexion of the heel and foot against plantarflexion), and a positive gap sign (i.e., a palpable, tender gap in the tendon).⁴⁸ The Thompson squeeze test is performed with the patient in the prone position and the examiner squeezing the calf (Figure 223-24). It normally produces plantarflexion. The Thompson test produces no motion or markedly decreased motion if the Achilles tendon is ruptured (Figure 223-25). Active range of motion and plantarflexion are preserved due to intact extrinsic muscles of the foot. It is always important to compare against the uninjured side as some motion may be retained even with injury. Obtain radiographs to rule out a fracture. This includes bedside ultrasonography of the Achilles tendon (Figure 223-26) to detect a partial or complete rupture.³⁴ This is especially useful when the differential diagnosis includes tendinitis versus a partial tendon rupture.

FIGURE 223-26. Ultrasound of an Achilles tendon rupture. (Used with permission of Emory Emergency Medicine Ultrasound Section.)

TREATMENT

Treatment in the Emergency Department is aimed at conservative measures.⁴⁸ It consists of NSAIDs, RICE (i.e., rest, ice, compression, and elevation), crutch use, and non-weight bearing. Apply a posterior long leg splint with the foot in 20° to 25° of plantarflexion (i.e., the equinus position) to oppose the tendon ends. Many Achilles tendon ruptures require surgical repair.^{48,49} Arrange follow-up with a Podiatrist or Orthopedic Surgeon within 24 to 48 hours.

DIABETIC FOOT CARE

Diabetic patients are vulnerable to many systemic complications of their disease.^{50,51} The diabetic foot syndrome is a major complication due to the pathogenic effects of plantar pressure on the foot. The three main risk factors leading to the development of serious cutaneous injury and infection include microcirculatory insufficiency, neuropathic changes, and an altered immune system. Diabetic foot syndrome is commonly triggered by ill-fitting shoes, poor foot hygiene, overlooked foreign bodies, callus formation, preexisting dry scaly skin with fissures, and possible underlying structural deformities.⁵² The goal of diabetic foot care is preventive to avoid plantar pressure and formation of plantar lesions, especially ulcers.⁵³

The diabetic patient faces a much higher likelihood of complications from the development of usually benign conditions due to plantar pressure (e.g., corns, calluses, paronychia, ingrown toenails, and ulcers).⁵¹ The diabetic patient may not be aware of the development of these conditions because of the loss of protective sensory functions. The impact of these complications to the diabetic foot is staggering. A significant percentage of diabetics with a foot ulcer will eventually require an amputation.⁵⁴ **Early and aggressive diagnosis and treatment of common diabetic foot disorders is essential to maximize the chances for wound healing and reduce the likelihood of complications.**

The medical history and clinical examination are the most important aspect of evaluating the diabetic foot.⁵⁰ **Perform a careful dermatologic, neurologic, orthopedic, and vascular examination as well as an assessment of the patient's footwear.** A thorough review of the physical examination and assessment of the diabetic foot is beyond the scope of this chapter.

Radiographic evaluation is mandatory if osteomyelitis is suspected. Characteristic changes include soft tissue swelling, osteolysis, and periosteal elevation. The formation of a sequestrum (i.e., a highly opaque and smooth island of bone surrounded by areas of decreased bone density) may be seen. Radiographic evaluation often lags behind the clinical evidence. A bone scan or magnetic resonance imaging is more sensitive than plain radiographs in making an early diagnosis of osteomyelitis.

TREATMENT

Educate the diabetic patient regarding foot care. Instruct the patient on proper footwear (e.g., good fit, high toe box, a round toe, good support of the heel and arch), inserts to accommodate any plantar lesions, and soft leather. Instruct the patient to check their shoes for any foreign bodies, rough spots, or any pressure points at the time of purchase and daily before donning the shoe. Caution the patient to avoid extreme temperatures from the environment or when cleansing the feet. Limit standing to 20 to 30 minutes at a time if a foot lesion is present.

Treat hyperkeratotic lesions the same as for nondiabetics with periodic debridement. Apply a corn pad with a central aperture or a horseshoe-shaped pad to relieve pain and disperse pressure at bony

prominences to the surrounding skin. Cut a hole in the patient's shoe over any nonweightbearing bony prominence to prevent irritation of the surrounding soft tissue. Apply a felt pad to cover the tops of any hammertoes. Apply a commercially available adhesive bunion pad or cut a bunion shield from 1 cm thick felt over a bunion or bunionette deformity.

Diabetic patients must be extra vigilant in caring for their toenails.^{50,51} Some authors recommend that diabetics should not cut their own nails, corns, or calluses. Ingrown toenails (Chapter 218) are treated the same as for nondiabetics. **Treat mycotic infections aggressively.** These conditions are often unnoticed by diabetic patients because of their peripheral neuropathy and the loss of protective sensation. Mycotic lesions often present at an advanced stage. A simple but thorough vascular examination is mandatory if an infected or advanced lesion is present. Absent or diminished pedal pulses (i.e., posterior tibial and dorsalis pedis) may indicate lower extremity ischemia. This requires further vascular evaluation, either through noninvasive testing or outpatient management from a Vascular Surgeon.

The most common location for foot ulcers is the plantar surface of the forefoot. These are essentially pressure ulcers. Instruct the patient to avoid mechanical stress on the injured extremity as ongoing trauma prevents healing. Treatment from the Emergency Department is simple and consists of the application of a wound dressing, antibiotics if there is infection, bed rest or the use of crutches, and referral to a Podiatrist or Orthopedic Surgeon. The consultant may use sharp debridement of devitalized tissue from the wound area to promote wound healing.

A moist wound environment is important for wound healing. There are many commercially available foot care products with little proven efficacy. They may confuse the patient. A simple and clear-cut discharge strategy is wet-to-dry dressing changes twice a day. This can be continued in the home. There is controversy regarding the use of topical agents and foot soaks. Neither one has been shown to be beneficial in the healing of a diabetic foot ulcer. Cover the lesions with a pad to disperse pressure to the surrounding skin and protect the ulcer. Instruct the patient to place a pillow under the calf and allow the heel to overhang if there is a heel ulcer.

Treat infected ulcers aggressively with systemic antibiotics. Hospital admission is often required. Mild and most moderate infections can be treated with oral antibiotics on an outpatient basis with an appropriate candidate (e.g., reliable patient and good home support). The selected antibiotic must achieve good tissue levels and sufficiently cover most skin pathogens, especially aerobic gram-positive cocci. Wound infections are commonly polymicrobial with some drug resistance. Wound cultures may help guide therapy and focus the antibiotic choice. These patients require close follow-up within 24 to 48 hours for a wound check and a review of antibiotic therapy when the culture and sensitivity results are available.

Severe infections, with or without systemic symptoms, require hospital admission for parenteral antibiotics and surgical consultation. An experienced consultant will decide if the wound can be debrided at the bedside or necessitates the Operating Room. **Administer broad-spectrum intravenous antibiotics immediately after wound and blood cultures are obtained. The antibiotic regimen must cover aerobic and anaerobic gram-positive cocci as well as gram-negative organisms.** Examples include imipenem-cilastatin or vancomycin plus aztreonam plus metronidazole. A beta-lactamase inhibitor (e.g., ampicillin-sulbactam) or clindamycin plus a fluoroquinolone is recommended for less severe infections.

Osteomyelitis is a difficult infection to cure and requires a long course of antibiotics. A 6 week course of antibiotics is recommended, including 1 to 2 weeks of parenteral therapy. Surgical treatment may

include debridement of the infected bone if this will not compromise long-term foot function. Debridement will increase the likelihood of a cure and shorten the course of required antibiotics. Removal of the infected bone may correct any underlying bony deformity that may have originally caused the ulcer. Vascular reconstruction and/or amputation are considered for appropriate candidates.

Adjunctive medical therapy includes improving blood glucose, control of comorbid conditions, and medical nutrition to improve the healing potential of foot wounds. A discussion of these topics is beyond the scope of this chapter.

ONYCHOMYCOSIS (FUNGAL TOENAIL INFECTIONS)

Approximately 20% of the U.S. population between the ages of 40 and 60 have fungal nail disease.⁵⁵ Onychomycosis is most often caused by dermatophytes of the *Trichophyton* genus. Nondermatophytes (e.g., molds or yeasts) are also causative organisms. Onychomycosis may occur posttraumatically. It is commonly seen in the first and fifth toenails where the greatest shoe friction occurs. The infection occurs under or within the nail plate and causes proliferation of keratinized debris under the nail. The nail will become opaque, discolored, thickened, and brittle if the infection progresses (**Figure 223-27**). Formal diagnosis is made by identifying hyphal fragments upon microscopic examination of nail scrapings placed in a potassium hydroxide solution. Onychomycosis is usually diagnosed based upon the clinical examination and therapy is often empiric. “Skipped” normal nails are often seen in fungal toenail infections. Psoriasis or other inherited nail dystrophies involve all 10 nails.

Four major types of mycotic nail infection have been identified. These include distal subungual onychomycosis, white superficial onychomycosis, proximal white subungual onychomycosis, and candidal onychomycosis. These various entities differ in the pattern of fungal invasion of the nail plate and the causative organism. Clinical symptoms of mycotic toenail infections include brittleness, color changes, hyperkeratosis, onycholysis (i.e., separation of the nail from its bed), and paronychia inflammation (**Figure 223-27**).⁵⁶ Distal subungual onychomycosis is the most common type. It affects the most distal part of the nail bed and nail plate. White superficial

onychomycosis is seen mainly in toenails. It produces a white, brittle appearance due to direct invasion of the nail plate’s surface. Proximal white subungual onychomycosis is very rare. It is due to fungus invading the cuticle and turning the proximal nail plate white.

The morphology of the nail plate infection at the time of presentation may help determine the need for additional therapy. Dermatophytoma or longitudinal streaking with nail plate changes is produced by keratin debris and filled with dermatophytes. This produces a relatively inaccessible foci of infection. Lateral nail plate involvement or onycholysis results in a separation of the nail plate from the nail bed, reduces the vascular access to the nail plate, and limits the penetration of systemic therapy. Thick nails > 2 mm may indicate matrix involvement and keratinaceous debris. This can limit drug diffusion regardless of the delivery system. These presentations all limit the access of topical and systemic agents to the site of infection and all require adjunctive therapy that is directed to the physical removal of the keratinaceous debris. Mechanical or chemical debridement is essential for effective therapy.⁵⁷

TREATMENT

Treatment of onychomycosis may be divided into topical, systemic, and surgical therapies.⁵⁸ Topical agents have been found to be effective if the fungal infection is limited to the distal portion of the nail plate.⁵⁹ Simple mechanical filing of the nail plate, curettage of the necrotic subungual tissue, trimming of the nail plate, and topical antimycotic therapy are often effective.

Treatment of more advanced infections begins with an empiric trial of an oral antifungal agent.^{56,58,60} Itraconazole (e.g., Sporanox) is a newer member of the azole family and has a very broad antimycotic spectrum of action. It is effective in the treatment of dermatophytes, yeasts, and some nondermatophyte molds. Terbinafine (e.g., Lamisil) is an orally active allylamine that works against dermatophytes but not yeast. Both itraconazole and terbinafine are associated with a significantly shorter treatment time and higher clinical cure rate over the older systemic agents (e.g., griseofulvin). Studies have shown that pulse therapy is an effective treatment regimen for itraconazole and terbinafine.⁶¹⁻⁶⁵ This consists of 1 week of daily treatment each month for 3 to 4 consecutive months. Inform patients of any potential symptoms, side effects, and drug reactions. Obtain a baseline liver profile, chemistry panel, and complete blood count. **There is a small risk of hepatotoxicity from oral antifungal agents.** It is recommended that a Primary Care Physician, Podiatrist, or Orthopedist prescribe these medications rather than an Emergency Physician. Any patient receiving long-term antifungal therapy for onychomycosis must undergo periodic laboratory monitoring.

More extensive involvement or failure of outpatient therapy may require removal of the nail plate, an oral antifungal agent, and local wound care. Apply a topical antifungal agent twice daily while the new nail plate develops. Refer the patient to a Podiatrist for refractory chronic onychomycosis, especially the patient who has diabetes or vascular disease. Surgical treatment may include nail plate removal with nail bed debridement (with or without chemical destruction of the nail bed matrix). Close follow-up is mandatory.⁶⁶

SUMMARY

Foot complaints are commonly encountered in the Emergency Department. Many of these conditions can be managed using easy, simple, and straightforward techniques. Refer the patient to a Podiatrist or Orthopedic Surgeon for plantar lesions in high-risk patients (e.g., poor wound healing, diabetes, peripheral neuropathy), conditions needing a specialist, or chronic conditions needing continuing care.

Relief of Choking and Acute Upper Airway Foreign Body Removal

Guy Shochat and Jacqueline Nemer

INTRODUCTION

The National Safety Council reports that airway foreign body (FB) obstruction accounts for over 4800 adult and pediatric deaths per year in the United States.¹ Accidental FB obstruction of the airway is the fourth leading cause of accidental death in children less than 6 years of age.¹ Contemporary data are lacking regarding the type of obstructing object in fatal cases. Older research data for nonfatal choking episodes in children reported a more common association with food to nonfood objects by a 2:1 ratio. There is some variation but the most common objects are candy (e.g., hard candy which leads softer candy and gum); peanuts which lead the food items category; and coins which lead the nonfood group.² Mortality due to airway FB obstruction is bimodal and increases again in the elderly.¹ Food impaction is the primary etiology in the elderly, institutionalized, and those with cognitive impairment or intoxication.²⁻⁴

ANATOMY AND PATHOPHYSIOLOGY

Developmental differences in the pediatric airway make visualization and removal of FBs more difficult than in the adult patient. The pediatric tongue occupies a larger percentage of the oral cavity and the oropharynx. The pediatric epiglottis is larger, U-shaped, and more cephalad. The pediatric epiglottis does not attain the adult position until age 4. The narrowest portion of the pediatric airway and a likely site of obstruction is below the vocal cords at the level of the cricoid cartilage, making removal more difficult and more likely to require endoscopy.³⁻⁶

The clinical presentation and patient management are dependent on the anatomic site of obstruction, the degree of obstruction, and the size of the FB. Patients with a supraglottic obstruction classically present with inspiratory stridor while those with an infraglottic obstruction present with expiratory wheezes. Infraglottic FBs usually lodge in the trachea or the main stem bronchus and will require instrument removal. A FB simply contacting the vocal cords while moving through the glottis may result in laryngospasm which can completely obstruct the airway, even after the expulsion of the FB.^{5,6}

Partial airway obstructions generally allow at least limited amounts of air passage and the potential for removal by the patient's cough reflex. Complete airway obstructions can result in a silent cough followed by loss of consciousness if not cleared by coughing or assistive maneuvers. A larger FB is more likely to lodge at or above the vocal cords where it can cause a complete airway obstruction. Sharp, small, and thin FBs are more likely to partially obstruct between or below the vocal cords and result in difficulty breathing and dysphonia.^{5,7-9}

Pediatric and adult patients provide different clues to airway FB obstruction. Adults and older children typically indicate the "universal choking sign" by clutching or pointing to their neck and nodding affirmatively when asked if choking. The symptoms in an infant or toddler may range from tachypnea, subtle stridor, wheezing to respiratory distress, cyanosis, and unconsciousness.^{10,11}

DIGITAL REMOVAL (FINGER SWEEP)

Perform digital removal of an intraoral FB only when it is directly visualized in the patient's mouth or oropharynx.¹⁰ Blind finger sweeps are contraindicated to prevent inadvertently pushing the FB into a more distal location and converting an incomplete supraglottic obstruction into a difficult to remove and complete infraglottic obstruction.¹²

Open the patient's mouth and airway using the thumb and fingers of the nondominant hand to grab the tongue and mandible and then lift it anteriorly. Use a hooking action with the index finger of the dominant hand to dislodge and remove the FB.

The most important potential complication is the conversion of a partial airway obstruction into a complete airway obstruction. Local trauma can result in intraoral abrasions, bleeding, and dental trauma. The rescuer can sustain digital abrasions and lacerations from the patient's teeth. **Do not place your fingers into the mouth of a conscious patient as this can result in a significant bite injury.^{13,14}**

BACK BLOWS AND CHEST THRUSTS IN INFANTS

An uncoordinated swallow mechanism and the lack of molar dentition predispose the infant to an airway FB obstruction within their narrow and pliable glottis and trachea.¹⁵ **Perform back blows and chest thrusts on the infant with a witnessed or suspected airway FB obstruction who suddenly develops respiratory distress, appears cyanotic, or becomes unconscious.¹⁴**

Initiate back blows and chest thrusts to attempt to dislodge the obstruction in the conscious infant showing signs of airway obstruction.¹⁶ **Use this technique on infants less than 1 year of age. Use abdominal thrusts if the patient is over 1 year of age. Closely observe the infant but do not intervene if they are maintaining their airway as indicated by clear breathing and an effective cough. Their cough reflex may allow them to dislodge and expel the FB.¹⁰**

Support the infant's head and neck with one hand. Place the choking infant with their head lower than their torso in a prone position over the arm and resting on the thigh or the lap of the Emergency Physician (**Figure 224-1A**). **This head-down position allows gravity to assist in the expulsion of the dislodged FB.** Perform five firm back blows with the heel of a hand between the infant's shoulder blades (**Figure 224-1A**). Turn the infant face up in the supine position with their head still below the torso (**Figure 224-1B**). Use the heel of the hand (**Figure 224-1B**) or two or three fingers (**Figure 224-1C**) to deliver up to five chest thrusts over the sternum and depress the sternum ½ to 1 inch per thrust while avoiding the lower tip of the sternum. (**Figure 224-1B**). An alternative is to

FIGURE 224-1. Relief of an airway foreign body obstruction in the infant. **A.** Back blows using the heel of a hand. **B.** Chest thrusts using the heel of a hand. **C.** Chest thrusts using two fingers. **D.** Chest thrusts using both thumbs.

use both thumbs (**Figure 224-1D**). The use of thumbs is performed when one or two rescuers are present. Place both thumbs together over the lower half of the infant's sternum just below the intermamillary line. Encircle the infant's chest with both hands, spreading the fingers around the posterior thorax. Compress the sternum while squeezing the thorax to apply counterpressure. Repeat this sequence of back blows and chest thrusts until the FB is expelled or the infant becomes unresponsive.¹⁰

The procedure is successful when the FB is expelled. Observe the infant closely following the expulsion of the FB for any signs of persistent respiratory distress due to an incompletely expelled FB or injury from the removal techniques.

The Emergency Physician must first check the mouth and remove any obvious FB in the unresponsive infant. **Blind finger sweeps are always contraindicated.** Case reports describe wedging of FBs into more distal locations and converting a partial airway obstruction into a complete airway obstruction.⁷ The Emergency Physician must immediately initiate bag-valve-mask ventilation in the apneic infant. Continue the cycles of back blows and chest thrusts with bag-valve-mask ventilation while preparing for immediate intubation.

Injuries may result from back blows and chest thrusts (e.g., back and chest wall contusions). Vigorous back blows can result in rib fractures and lung trauma (e.g., pulmonary contusion). Nausea and vomiting can occasionally result. Chest thrusts may result in rib and sternal fractures, myocardial contusions, lung puncture or

contusion, pneumothoraces, and intraabdominal injury.^{7,10} **These potential complications are serious. Failure to relieve the airway FB obstruction can result in death.**

The Emergency Physician must maintain a low threshold for performing back blows and chest thrusts to relieve an airway FB obstruction in infants. Airway FB obstruction in an infant is more common, more difficult to assess, and more often fatal than in an older child, adolescent, or adult. **The key steps include positioning the infant head down over the Emergency Physician's arm or leg with their head lower than their trunk, performing five back blows alternating with five chest thrusts, and repeating this sequence continuously until the FB is expelled.**

HEIMLICH MANEUVER

Dr. Henry Heimlich first proposed the Heimlich maneuver in 1974.¹⁷ Controversy soon followed as he publicly denounced the recommendations made by the American Red Cross and the American Heart Association. He claimed that back blows previously listed as a first-line treatment were "death blows" and that various national organizations were involved in "Watergate cover-ups" intended to prevent acceptance and widespread use of his maneuver.

No prospective clinical trials have been reported on the various techniques used to relieve an airway FB obstruction. Physiologic data demonstrate that each technique produces varying effects on

intrathoracic pressure and airflow to overcome the static resistance of the obstructing FB.¹⁸ Back blows generate a substantial increase in intrathoracic pressure over a very short time and potentially dislodge an airway FB without its expulsion from the airway. Abdominal thrusts generate more prolonged increases in airway pressure and flow rates, theoretically allowing for expulsion of the dislodged FB. The Emergency Physician must be prepared to quickly utilize a combination of these techniques for the dislodgement and expulsion of an airway FB obstruction.^{10,11,13}

Abdominal thrusts can be a lifesaving procedure but they are also associated with a wide range of serious complications. Reported complications include solid organ injury (i.e., liver, spleen, and pancreas), perforation of the esophagus or stomach, diaphragmatic rupture, fractures (e.g., ribs, sternum, or vertebra), hemothorax, pneumothorax, or a pulmonary contusion.¹⁹⁻²² **Any patient that is symptomatic following this maneuver must be thoroughly evaluated and closely observed for potential complications.**

ABDOMINAL THRUSTS IN THE PATIENT OVER 1 YEAR OF AGE

Abdominal thrusts may be considered in the conscious patient over 1 year of age with a witnessed or presumed aspiration who has findings of complete airway obstruction (i.e., cannot speak, cough, or breathe effectively).¹⁰ Older children and adult patients will often present and be grasping or pointing to their neck with the “universal choking sign” (Figure 224-2).¹¹ Young children will often have a history or presentation consistent with an airway FB obstruction. This technique can be performed from behind the patient if they are conscious and have signs of a complete airway obstruction. **Abdominal thrusts should NOT be performed in patients less than 1 year of age due to the significant risk of liver injury.**^{10,14} The patient’s

FIGURE 224-2. Abdominal thrusts in a conscious patient.

cough reflex may expel the partial obstruction if they are able to breathe, cough, and speak. A patient with a partial FB obstruction must be closely observed. The partial FB obstruction may convert into a complete airway obstruction. **Abdominal thrusts should be performed only for a complete airway obstruction.**

Stand directly behind the conscious patient (Figure 224-2). Wrap both arms around the patient’s waist. Make a fist with one hand and place this hand with the thumb side of the fist against the midline of the patient’s upper abdomen between the ribcage and umbilicus. The other hand is placed over the fist and grasps the fist (Figure 224-2). Press inward with a deliberate and quick upward thrust. **Limit the force of the thrust to the hands without squeezing the ribcage. Repeat these quick upward thrusts until the FB is expelled or the patient becomes unresponsive.** Observe the patient for signs of respiratory distress from persistent obstruction or from injury sustained during abdominal thrusts after the FB is expelled.

The next step in the Basic Life Support (BLS) protocol is to perform abdominal thrusts if the patient loses consciousness. The Emergency Physician should intubate and provide advanced care if the patient become unresponsive.

Incorrect hand placement can result in sternal and rib fractures. Significant but rare complications may occur including thoracic and intraabdominal injuries. Perform close observation and evaluation on any patient who is symptomatic after undergoing abdominal thrusts. Failure to relieve an airway FB obstruction can result in death.

ABDOMINAL THRUSTS IN THE UNCONSCIOUS PATIENT

Perform abdominal thrusts in the patient with a witnessed or suspected airway FB obstruction, if the previously described maneuvers have failed, or in the unresponsive patient.¹⁴ **Do not perform this maneuver in patients less than 1 year of age due to the significant risk of liver injury.**

Place the patient supine on the floor. A bed is not firm enough to allow the appropriate generation of intraabdominal pressure. Open their mouth. **Perform a finger sweep only if a FB is clearly visible.** Place the heel of one hand in the midline of the abdomen and just above the umbilicus. Place the other hand over the first (Figure 224-3). Apply

FIGURE 224-3. Abdominal thrusts in the unconscious patient.

five rapid and forceful thrusts downward and upward, forcing the diaphragm upward and compressing the lungs. Reassess the patient's airway. Inspect their mouth for a FB. Remove the intraoral FB if it is visible. If the FB is not visible, repeat the abdominal thrusts or attempt another technique.

One case study reported that increased airway pressure was generated using a knees-to-chest approach in the supine position. While there are no further studies to support this technique, it may be a simple adjunct when other methods have failed.²³

Closely observe the patient after the FB is expelled for signs of respiratory distress from persistent obstruction or from injury from the abdominal thrusts. Incorrect hand placement can result in sternal and rib fractures. Place the patient in the semirecumbent position or sitting upright if no contraindications exist after the FB is removed.

OBSERVATION UNTIL REMOVAL IN THE OPERATING ROOM

It is best not to manipulate the airway or attempt intubation in a stable patient with an airway FB who is moving air and breathing. The airway may be best controlled in the Operating Room at the time of the actual FB removal. Manipulation of the airway can result in a FB becoming dislodged and turn a partial airway obstruction into a complete airway obstruction. The bronchoscopy equipment is available for urgent use if needed in the Operating Room.

The timing of endoscopy and airway FB retrieval must be based upon each individual patient. It is essential not to waste time if impending airway obstruction exists or the patient is unstable. This is an emergent situation warranting immediate notification and mobilization of an Anesthesiologist, Otolaryngologist and/or Pulmonologist, and the Operating Room.

It is appropriate to wait for the NPO (nothing by mouth) status to decrease the risk of aspiration which can further compromise the situation if the patient is stable. It is appropriate to wait in a stable patient to assemble the appropriate and best team to care for the patient. Using personnel who are unfamiliar with endoscopy can create a compromised and stressful situation.

DIRECT LARYNGOSCOPY

It is possible to remove FBs located within the hypopharynx in a stable patient.²⁴ **It may sometimes become necessary to attempt FB removal by direct laryngoscopy in a decompensating patient when the specialized consultants are not available.** Typical FBs that may be removed include pieces of food and fishbones. Anteroposterior and lateral soft tissue radiographs of the neck may localize a radiopaque FB. There has been an increase in computed tomography (CT) scans to identify FBs lodged in the pharynx, hypopharynx, or esophagus due to their superiority over plain radiographs. Their use needs to be weighed against the risk of radiation exposure.^{3,4,9} Fiberoptic laryngoscopy can be used to locate and identify a FB.^{5,7-9} Experienced and trained Emergency Physicians can retrieve a FB with graspers via an instrument channel on a flexible fiberscope (Chapter 28). The technique of awake topically anesthetized direct laryngoscopy can be used to locate and remove a supraglottic FB.

EQUIPMENT

- Intubation equipment (Chapter 18)
- Percutaneous transtracheal jet ventilator
- Cricothyroidotomy equipment (Chapter 32)
- Suction source, tubing, and catheter
- Airway forceps (i.e., Boedeker, Magill, or Tylke)

- Laryngoscope with a variety of blades (Chapter 18) or a video laryngoscope (Chapter 20)
- Topical or nebulized anesthetic
- Fiberoptic nasopharyngoscope or bronchoscope (Chapter 28)
- Oxygen

Direct laryngoscopy and bronchoscopy in a child or adult with an airway FB is a dangerous situation. The procedure may result in a partial airway obstruction becoming a complete airway obstruction. **Always have a cricothyroidotomy tray and/or percutaneous transtracheal jet ventilation device immediately available.**

All equipment must be selected, assembled, and ready for use. Place the patient in full monitoring (pulse oximeter, cardiac monitor, and noninvasive blood pressure cuff). Apply a topical anesthetic spray to the oropharynx and the base of the tongue to blunt the gag reflex. Place the patient supine or semirecumbent. Administer a small dose of an intravenous sedative if required and not contraindicated.

Slowly and gently insert the laryngoscope blade. An alternative to a traditional laryngoscope is a video laryngoscope.²⁵ The video laryngoscope may provide a better field of view with less manipulation. **Do not immediately insert the laryngoscope blade all the way.** Stop frequently to lift the laryngoscope and look for the FB. Slow insertion and frequent looks will prevent the laryngoscope blade from pushing the FB further into the airway. Elevate the patient's tongue and jaw. Grasp the FB with an airway forceps.^{24,26} If the FB is too large or impacted, it may need to be crushed with the forceps to securely grasp it as one piece.²⁷ Withdraw the forceps with the FB followed by the laryngoscope.

One case report describes passing a Foley catheter distal to the FB under direct visualization with a laryngoscope.²⁷ The balloon was then inflated with 5 mL of air and subsequently pulled back until the FB could be grasped and removed with a Magill forceps. There were no reported complications. It should be noted the FB in this case was impacted within the esophagus at the level of the cricoid cartilage. Do not use this technique with subglottic airway foreign bodies since retraction of a dilated catheter balloon through the glottic structures may cause injury, edema, bleeding, and further worsen the obstruction.

One review reported no complications with subglottic FB removal when utilizing Magill forceps under direct laryngoscopy.²⁸ Potential complications include oropharyngeal trauma resulting in glottic edema and bleeding.

All patients who have undergone FB retrieval require at least 4 to 6 hours of airway observation in a monitored setting to assess for persistent or delayed respiratory distress resulting from incomplete removal or procedural complications. Administer racemic epinephrine treatments and intravenous dexamethasone as needed. Prolonged observation is warranted along with consideration of an admission to the Intensive Care Unit if these treatments are needed. Discharge from the hospital is acceptable when the patient is breathing comfortably and no longer in danger of airway compromise following several hours of observation. Some patients may be discharged to home the same day. Others may require multiple days of airway support and observation. Potential complications include oropharyngeal trauma resulting in glottic edema and bleeding.

OROTRACHEAL INTUBATION

Orotracheal intubation can be attempted if the airway obstruction progresses rapidly and the patient cannot ventilate. Intubation can be used to force the FB into one main stem bronchus and allow ventilation of the other lung. One-lung ventilation will keep the patient alive until the FB can be removed.

Position the laryngoscope to visualize the larynx. Grasp the FB with an airway forceps and remove it if it is visualized. Intubate the patient if no FB is visualized. Insert the endotracheal tube if the patient is unable to ventilate. Advance the endotracheal tube as far as it will advance. Use a smaller endotracheal tube or a bougie if the first endotracheal tube will not advance. The patient will be able to be ventilated if this is successful. The endotracheal tube can then be withdrawn and positioned with its tip above the carina to try to optimize ventilation. **As an alternative, properly insert and position the endotracheal tube above the carina and then advance a bougie through the endotracheal tube in attempt to move the FB distally.**

Always be prepared to perform a cricothyrotomy (Chapter 32) or transtracheal jet ventilation (Chapter 31). Transtracheal jet ventilation allows for short-term oxygenation, is temporary, and may allow time for endoscopy for the FB retrieval.

MECHANICAL DEVICES

The LifeVac device was developed for clearing a FB obstruction from the upper airway (LifeVac LLC., Springfield Gardens, NY).²⁹ The kit contains the LifeVac device, adult and pediatric face masks,

and instructions for use (**Figures 224-4A and 224-4B**). It is a single-use suction device that is portable and used with the included face mask (**Figure 224-4C**). The device works like a toilet plunger (**Figure 224-4D**). The face mask makes a tight seal to the face and uses pressure to dislodge the FB from the airway. It can be used by the lay public or health-care workers. The company website notes it generates 300 mmHg of suction and three times the force of any choking pressure.

The Dechoker device was developed for clearing a FB obstruction from the upper airway (Dechoker, Prospect, KY). It looks like a big syringe with a face mask and a tube at its distal end (**Figure 224-5A**). The company makes a wall mount that is often placed by first aid kits (**Figure 224-5B**). The device is available in size-specific kits of toddler, child, and adult size. The kit contains the Dechoker device with a size-specific face mask and instructions for use (**Figures 224-5A and 224-5B**). It is a single-use suction device that is portable and used with the attached face mask (**Figure 224-5C**). The face mask makes a tight seal to the face and uses pressure to dislodge the FB from the airway. It can be used by the person choking, lay public, or health-care professionals (**Figures 224-5D and 224-5E**).

D

E

FIGURE 224-5. (Continued)

These above mechanical devices have not undergone clinical trials. Their use, for now, must be a last effort to relieve the choking victim if other methods fail. First try abdominal thrusts, back blows, digital removal, laryngoscopy if the equipment is available, and intubation if the equipment is available.

AFTERCARE

Most patients should be breathing spontaneously after the extraction, removal, or retrieval of an airway FB. An endotracheal tube may rarely, in the presence of significant laryngeal or tracheobronchial edema, need to remain in place temporarily. This would require admission to an Intensive Care Unit. Humidified oxygen is helpful to keep the airway moist and prevent mucous crusts from forming. A postprocedural radiograph will help to determine any complications (e.g., subcutaneous air, air in the soft tissues, a pneumothorax, or any changes to the lung fields) following the extraction. The radiograph will confirm the endotracheal tube position.

All patients who have undergone FB extraction, removal, or retrieval require at least a few hours of airway observation in a monitored setting.³⁰ Racemic epinephrine treatments and intravenous Decadron can be administered as needed. Discharge from the hospital is acceptable when the patient is breathing comfortably and no longer in danger of airway compromise. Some patients may be discharged home the same day while others may require multiple days of airway support and observation.³⁰

COMPLICATIONS

Complications from the foreign bodies themselves include hypoxia leading to cerebral anoxia if not identified. Cardiac arrhythmias can occur from hypoxia or direct pressure on the left mainstem bronchus. Other complications include laryngeal or tracheobronchial edema from the FB or the instrumentation of the airway. Mucosal irritation can instigate a bronchitis, pneumonia, or tracheitis. A pneumomediastinum and/or a pneumothorax is possible. The complications specific for each technique have been described previously in the respective sections.

A FB in the hypopharynx can be pushed distally and result in a total airway obstruction. The FB needs to be quickly removed or pushed back down into one of the mainstem bronchi to allow ventilation of at least one lung or a surgical airway needs to be performed. Failure to react appropriately in this situation can result in asphyxiation and death.

SUMMARY

Airway FB obstruction is a significant cause of morbidity and mortality, especially in pediatric, debilitated, and elderly patients. Presentations can range from the obvious to the very subtle. Close observation is indicated to determine if the patient's own cough reflex can expel the FB for the awake patient. Stable patients can be observed closely. Manage a stable patient with an airway FB with a planned endoscopic removal in a setting that allows for endoscopic or surgical management if a complete obstruction occurs.

Age-appropriate BLS maneuvers should be performed in conscious patients with a complete airway obstruction or partial airway obstruction with severe respiratory distress.^{10,11} The patient requires emergent intubation for ventilation and airway management if they become unconscious. The Emergency Physician may attempt FB removal if it is visualized. A temporizing measure is to force the FB distally in the airway and allow for partial ventilation.

The flexible fiberoptic endoscopy can be used to localize FBs. Consultants are not always immediately available. Direct laryngoscopy can be used to localize and facilitate forceps removal of the FB.

This is especially true for the FB when it is low risk for fully obstructing the airway (e.g., a fish bone). Direct laryngoscopy can be used if a patient is deteriorating and requires management to prevent imminent complete airway obstruction. Observe all patients who have airway FB removal for complications if not admitted for observation.

Induction of Therapeutic Hypothermia (Targeted Temperature Management)

Eleanor Dunham

INTRODUCTION

Sudden cardiac death claims more than 350,000 victims in the United States every year.¹ The mortality rate for out-of-hospital cardiac arrest remains a staggering 65% to 95%, with only 10% to 20% of survivors discharged from the hospital with a good neurologic outcome.² **Therapeutic hypothermia for the treatment of comatose survivors of cardiac arrest is a proven therapy to improve survival and neurologic outcome.**³⁻⁵

Many consider therapeutic hypothermia to be a relatively new concept. Experiments with deep therapeutic hypothermia began in the 1940s with initially mixed results. In the 1950s, studies examined moderate hypothermia in the range of 26°C to 32°C (i.e., 78.8°F to 89.6°F) in comatose survivors of cardiac arrest and reported a trend toward improved outcomes but were complicated by difficult-to-control side effects. Additional animal studies of mild hypothermia in the range of 32°C to 35°C (i.e., 89.6°F to 95°F) in the 1980s and small clinical trials in the 1990s demonstrated that even mild hypothermia provided protective benefits with far fewer side effects.²

Two landmark randomized trials published in 2002 specifically examined the use of mild hypothermia in comatose survivors of witnessed cardiac arrests with initial rhythms of pulseless ventricular tachycardia or ventricular fibrillation.^{6,7} **Meta-analyses report that only seven patients need to be treated to save one life and only five patients need to be treated to prevent one poor neurologic outcome.**^{8,9} Utilizing strict screening criteria of these studies resulted in only 10% of screened patients being eligible. Follow-up studies suggest a wider benefit in patients with other rhythms at presentation, patients with cardiogenic shock, and those requiring percutaneous cardiac intervention (i.e., angioplasty and stenting).^{2,3,10-18}

Preliminary studies of therapeutic hypothermia for other indications including anaphylaxis, acute respiratory distress syndrome, heatstroke, myocardial infarction, near-drowning, near-hanging, pregnancy, strokes, status epilepticus, subarachnoid hemorrhages, toxins, and traumatic brain injury have reported only limited data or conflicting results.¹⁹⁻³² Recent studies have shown that therapeutic hypothermia in comatose pediatric patients who initially survived out-of-hospital arrest does not improve survival or neurologic outcome after 1 year.³³ The exception is studies of neonates with perinatal asphyxia that reported similar results to adult cardiac arrest with a number needed to treat of six for one favorable outcome.³ Extensive research since 2002 has been conducted to determine

the effectiveness of therapeutic hypothermia for other indications as well as the optimal timing, duration, target temperature, and techniques.

The International Liaison Committee on Resuscitation Recommendations (ILCOR) and American Heart Association (AHA) Resuscitation Guidelines for 2015 state that targeted temperature management is recommended between 32°C and 36°C and is to be maintained for at least 24 hours.³⁴ The exact temperature for induction and maintenance of hypothermia is unknown.³⁵⁻⁴⁰ ILCOR recommends against routine use of prehospital cooling with rapid infusion of large volumes of cold intravenous fluids immediately after return of spontaneous circulation (ROSC).³⁴

The AHA recommends that active rewarming should be avoided in comatose patients who spontaneously develop a mild degree of hypothermia after resuscitation from cardiac arrest during the first 48 hours after ROSC.⁴¹ They cited reasons such as not enough data, not part of Advanced Cardiac Life Support (ACLS) protocol, too technically difficult, or that it had not been considered.¹⁷ The induction of therapeutic hypothermia for comatose survivors of cardiac arrest is relatively straightforward in any Emergency Department. **The creation of collaborative protocols between Emergency Physicians, Intensivists, Cardiologists, and Neurointensivists is essential to producing the best outcomes at each institution.**

ANATOMY AND PATHOPHYSIOLOGY

The postcardiac arrest syndrome has recently been defined as a complex pathophysiologic process involving brain injury, myocardial dysfunction, systemic ischemia and reperfusion response, and the underlying persistent precipitating pathology.³ Brain injury is the reported cause of death in two-thirds of patients after an out-of-hospital arrest and one-quarter of patients after an in-hospital cardiac arrest.¹⁸ Multiple cellular mechanisms contribute to neuronal apoptosis and necrosis including the formation of free radicals, disruption of calcium homeostasis, excitotoxicity, altered gene expression, mitochondrial dysfunction, and inflammation. These cellular mechanisms at the tissue level lead to failure of cerebral autoregulation and ultimately hypotension, hypoxemia, brain edema, pyrexia, hyperglycemia, and seizures.³

The post-cardiac arrest state does not result in myocardial infarction but only myocardial stunning for 24 to 48 hours, producing a reduced ejection fraction and a reduction in end organ oxygen delivery.³ The accumulated oxygen debt activates an inflammatory endothelial response further worsening oxygen delivery. The vicious cycle of oxygen debt and resultant inflammation does not end with reperfusion. The burst of reactive oxygen intermediates further exacerbates the inflammatory response and organ injury. The resultant state of systemic ischemia with reperfusion response leads to intravascular volume depletion, changes in vasoregulation, decreased oxygen utilization and delivery, and an increased risk of infection.

The underlying persisting pathology that caused the cardiac arrest must be addressed. Acute coronary syndrome is strongly implicated in up to 50% of out-of-hospital cardiac arrests.¹² Elevations of troponin T are present in up to 40% of patients at the time of cardiac arrest suggesting an ongoing cardiac ischemia or injury hours prior to the cardiac arrest. Additional etiologies of the cardiac arrest to consider include pulmonary embolism, primary pulmonary disease, sepsis, drug toxicity, or severe hemorrhage.

Hypothermia improves outcomes through several proposed mechanisms.^{39,42} Metabolic demand is reduced 5% for each degree Celsius reduction in core body temperature. At the cellular level hypothermia decreases adenosine triphosphate demand preventing intracellular acidosis and stabilizing cell membranes. At the tissue

level, hypothermia leads to decreased vascular permeability at the blood-brain barrier thus decreasing edema. Hypothermia interrupts the inflammatory cascade by inhibiting neutrophils, reduces the production of proinflammatory cytokines, and helps to prevent the free radical production associated with reperfusion injury.

INDICATIONS

Hypothermia is most effective in patients meeting the strict inclusion criteria of the initial landmark studies. Begin the induction of hypothermia in the Emergency Department for comatose survivors of cardiac arrest with a presumed cardiac etiology, an initial rhythm of ventricular fibrillation or pulseless ventricular tachycardia, and between 18 and 75 years of age.^{3,9} Studies have demonstrated improved outcomes in patients with other initial rhythms (e.g., pulseless electrical activity and asystole), comatose survivors of in-hospital cardiac arrest, patients requiring percutaneous cardiac intervention, and those suffering from cardiogenic shock.^{12,13,15,16,39,43} Consider the induction of therapeutic hypothermia when the cardiac arrest is witnessed, there is < 30 minutes from the time of the collapse to the start of resuscitative efforts, it is < 60 minutes from collapse to ROSC, the patient has a core body temperature > 35°C (i.e., 95°F), and blood pressure can be maintained > 80 mmHg with or without intravenous (IV) fluid boluses and pressors. The benefits have not been shown for in-hospital arrest.⁴⁴ The use of therapeutic hypothermia in this group is currently being studied further. Refer to **Figure 225-1** regarding a sample induction of therapeutic hypothermia checklist and clinical pathway.

CONTRAINDICATIONS

Hypothermia is contraindicated in patients with a known status of do not resuscitate (DNR) or do not intubate (DNI), a terminal illness, severe comorbidities, multiorgan failure before arrest, or who are comatose due to a noncardiac etiology. Patients with a preexisting coagulopathy or pregnancy have been excluded from most studies. One case of successful therapeutic hypothermia in pregnancy has been reported.⁴⁵ Other contraindications include patients in whom prehospital or in-hospital resuscitation was initiated greater than 15 to 30 minutes after collapse, patients with > 60 minutes from the time of arrest to the ROSC, patients who are persistently hypoxic (e.g., SpO₂ < 85%) for greater than 15 minutes after the ROSC, patients with an arrest that is related to blunt or penetrating trauma, patients in whom greater than 6 hours have elapsed since the ROSC, and patients who spontaneously awoken with a normal mental status. Do not induce hypothermia during cardiopulmonary resuscitation as this decreases ROSC.^{46,47} Wait until the patient has ROSC.

EQUIPMENT

■ GENERAL SUPPLIES

- Arterial line equipment and supplies (Chapter 72)
- Nasogastric tube equipment and supplies (Chapter 75)
- Cardiac monitor
- Ventilator
- Orotracheal intubation equipment and supplies (Chapter 18)
- Venous access equipment and supplies (Chapters 59 and 61)
- Analgesics (e.g., fentanyl, morphine, or meperidine)
- Sedatives (e.g., propofol, Ativan, or Versed)
- Neuromuscular blockers (e.g., pancuronium, vecuronium, or rocuronium)
- Defibrillator-cardioverter unit and supplies (Chapter 40)

■ COOLING SUPPLIES

- 4°C sterile normal saline or lactated Ringer's
- Ice packs or ice water-soaked blankets
- Core temperature probe and monitor (e.g., esophageal, rectal, or urinary)

■ EXTERNAL COMMERCIAL COOLING DEVICES (FIGURES 225-2 AND 225-3)

- Excel Cerebral Cooling System (Cryothermic Systems Inc., Broadview Heights, OH)
- Gaymar Medi-Therm III (Stryker, Orchard Park, NY)
- Arctic Sun Temperature Management System (Medivance Inc., Louisville, CO)
- Cincinnati Sub-Zero Blankets (Cincinnati Sub-Zero Products Inc., Cincinnati, OH)
- InnerCool STx Surface Pad Systems (Zoll Medical Corp., Chelmsford, MA)
- Thermosuit (Life Recovery Systems, Waldwick, NJ)
- CoolGuard 3000 (Zoll Medical Corp., Chelmsford, MA)
- MediTherm Cooling Blankets (Stryker, Orchard Park, NY)
- Altrix Cooling Unit (Stryker, Orchard Park, NY)
- EMCOOLS FlexPad Medical Cooling System (EMCOOLS, Austria)
- Mistral Cooling Unit (37 Degree Co., Netherlands)

■ INTERNAL ENDOVASCULAR COOLING DEVICES (FIGURE 225-4)

- Accutrol Catheter (Zoll Medical Corp., Chelmsford, MA)
- Cool Line, Icy, & Quattro catheters (Stryker, Orchard Park, NY)

There is a nasal cooling system called Rhinochill (BeneChill, San Diego, CA) (**Figure 225-5**). These systems take advantage of the large surface area of the nasal cavity with an abundant capillary supply just below the mucosa as a heat exchanger. These systems may be used prehospital as well as in-hospital for the cooling of the post-cardiac arrest patient. This system is used in Europe and not currently available in the United States.

PATIENT PREPARATION

Carefully consider inclusion and exclusion criteria for each individual patient utilizing preestablished institution-specific protocols. The risks, benefits, potential complications, and aftercare of the procedure should be explained to the patient's representative and an informed consent obtained whenever possible. The postarrest patient will or should be intubated, have continuous pulse oximetry and cardiac monitors, and have frequent automated cuff or continuous arterial line blood pressure monitoring.

Perform a detailed examination to document a postarrest comatose state and the patient's baseline neurologic status (e.g., Glasgow coma scale, pupillary light reflex, corneal reflex, facial movements, eye movements, gag, cough, and motor response to painful stimuli). The retention of any neurologic function during or after cardiopulmonary resuscitation suggests a good prognosis. **The absence of neurologic function immediately after the ROSC is not a reliable predictor of a poor outcome.** The reliability of the neurologic exam to predict a poor outcome is time dependent. The absence of pupillary light reflexes, corneal reflexes, or motor responses to painful stimuli at day 3 provides the most reliable predictor of poor outcome.³

Prepare the patient for therapeutic hypothermia. Turn the ventilator's warm humidified air function off so as not to warm the patient. Perform an electrocardiogram (ECG). Obtain basic laboratory analyses to include electrolytes, renal function, calcium, magnesium,

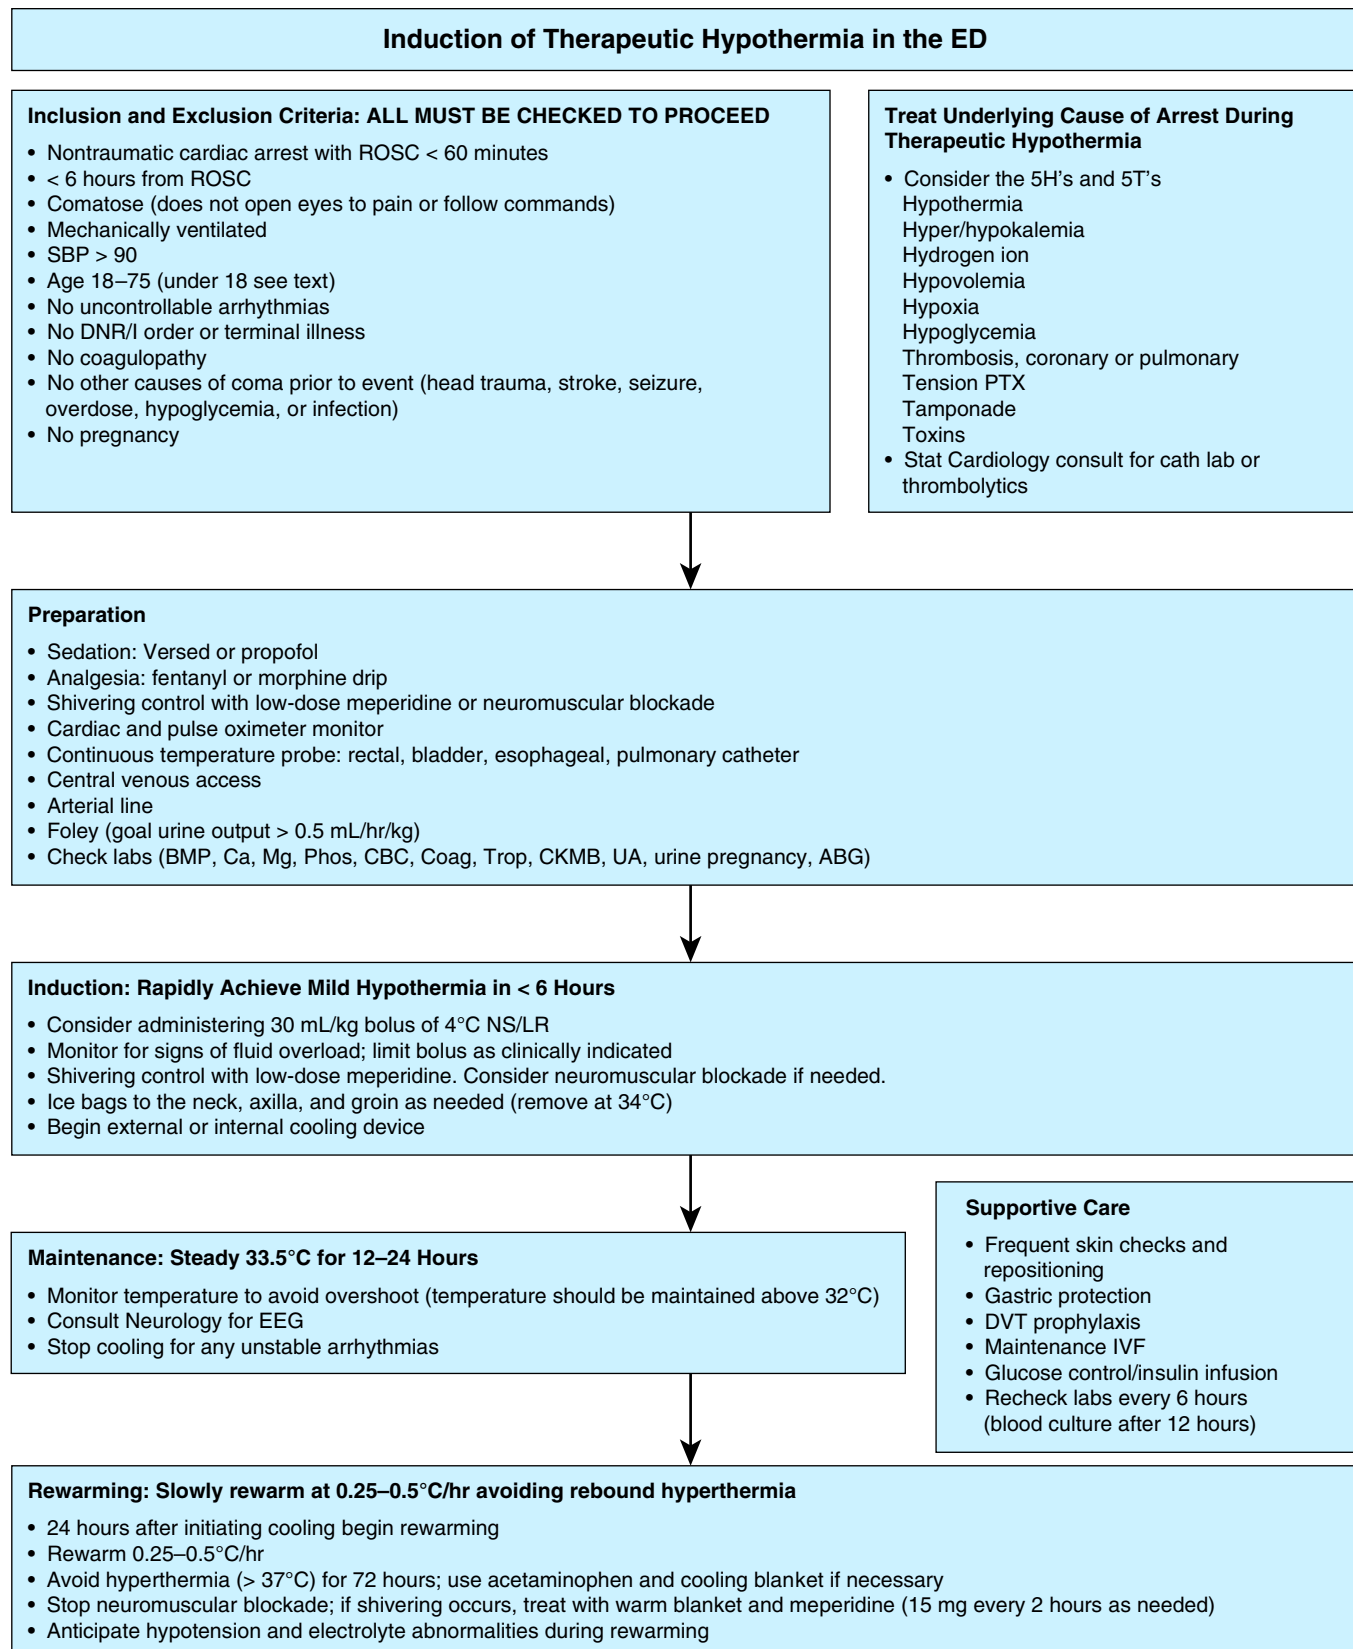

FIGURE 225-1. A sample induction of therapeutic hypothermia checklist and clinical pathway. ABG, arterial blood gas; BMP, basic metabolic panel; CBC, complete blood count; DVT, deep vein thrombosis; ED, Emergency Department; IVF, intravenous fluid; LR, lactated Ringer's; NS, normal saline; PTX, pneumothorax; SBP, systolic blood pressure; UA, urinalysis.

phosphorus, complete blood count, coagulation profile, cardiac markers, urinalysis, pregnancy, and arterial blood gas. Other laboratory analyses may include cortisol levels and thyroid function tests at the discretion of the admitting team. Titrate intravenous sedation and

analgesia for comfort with mechanical ventilation. Shivering increases oxygen consumption, requiring control with low-dose meperidine (e.g., 15 mg IV every 2 hours) and possibly neuromuscular blockade. Place a urethral catheter (Chapter 173) and monitor the urine output

with a goal of > 0.5 mL/hr/kg. Continuously monitor the core temperature with an esophageal, rectal, or urinary temperature probe. Place a nasogastric tube (Chapter 75). Apply defibrillator/pacing pads (Chapter 40) in case they are required during the therapeutic hypothermia process. Standard acute coronary syndrome and postresuscitation protocols otherwise apply.

TECHNIQUE

Therapeutic hypothermia is performed in three phases: induction, maintenance, and rewarming. There are multiple methods to perform all three phases. Detailed protocols from several institutions are available through the University of Pennsylvania's Center for Resuscitation Science at www.med.upenn.edu/resuscitation/

hypothermia/protocols.shtml. This site lists over 50 protocols for therapeutic hypothermia from various hospitals. **The goals of each phase always remain the same. Rapidly achieve a hypothermic state of 32°C to 36°C (i.e., 89.6°F to 96.8°F), maintain hypothermia for at least 12 to 24 hours, and then slowly rewarm at no faster than 0.25°C to 0.50°C (i.e., 0.45°F to 0.9°F) per hour.**

INDUCTION

Beginning the induction phase of therapeutic hypothermia in the Emergency Department is straightforward and inexpensive. The typical temperature decrease seen in survivors of cardiac arrest begins the process even before it starts. The infusion of 4°C Hartmann's solution, lactated Ringer's, or normal saline stored

A

in a temperature-controlled refrigerator provides a reliable and safe method for rapid induction.⁴⁷⁻⁵¹ Bolus 30 mL/kg or 1.5 to 2 L of fluid to create a 1.5°C to 2.3°C (2.7°F to 4.1°F) decrease in temperature.⁵²⁻⁵⁴ **Monitor the patient for signs of fluid overload and adjust the rate and total volume accordingly.** Smaller repeat boluses of 500 mL may be given when required.⁴² The application of ice packs to the head, neck, torso, and groin provides another safe and reliable method for rapidly decreasing temperature.⁵⁵ Patients requiring immediate angiography or admission to other locations may be transferred with these methods in place and without delay.^{12,15}

Several commercially available external and internal cooling devices listed in the equipment section allow the Emergency Physician to set and maintain a target temperature through continuous feedback from the patient's core temperature monitor. External systems utilize cooled circulated air, pads, or blankets. Internal systems require the placement of a femoral or subclavian central venous catheter with an endovascular cooling device. Initiate these devices while the fluid boluses and/or ice packs are applied.

To date there have been no studies comparing external versus internal cooling devices in cardiac arrest patients.⁵⁵ A manufacturer-sponsored study of therapeutic hypothermia in neurosurgical patients demonstrated that the endovascular device reached target temperature much faster (i.e., 35 versus 204 minutes), maintained a tighter control of target temperature, and had no significant increase in complications versus surface cooling.⁵⁶

Beginning the induction in the Emergency Department with cooled IV fluids and ice packs, followed by the immediate transfer of the patient to the Intensive Care Unit for the application of more expensive and delicate commercial cooling devices for maintenance of therapeutic hypothermia, provides a clinically effective and cost-effective approach in any institution. **Apply a commercial cooling device and continue the process of therapeutic hypothermia in the Emergency Department if there is any delay in transferring the patient to the Intensive Care Unit.**

MAINTENANCE

Stop cooling at 33.5°C (i.e., 92.3°F) to prevent overshoot.⁴² Use an external or internal cooling system with feedback control to maintain a core temperature of 32°C to 36°C (i.e., 89.6°F to 96.8°F).⁵⁷ Internal cooling devices have less variability.^{57,58} Other methods

include the use of cold wet blankets and ice packs placed around the head, neck, torso, and extremities. Although less expensive, these methods are more labor intensive, result in greater temperature fluctuations, and do not allow for controlled rewarming.⁵⁹ Maintaining hypothermia with fluid boluses alone is not possible.⁵⁹

Supportive therapy continues in the Intensive Care Unit (e.g., continuous cardiac monitoring, consideration of arterial monitoring, analgesics, sedatives, and neuromuscular blockade). Maintain a goal mean arterial pressure of 65 to 100 mmHg with a central venous pressure of 8 to 12 mmHg. Monitor urine output and laboratory values to best manage the resulting cold diuresis. Maintain tight glucose control (e.g., 108 to 144 mg/dL) to improve survival and neurologic outcomes.³ Decreased fever with therapeutic hypothermia increases the survival.⁶⁰

REWARMING

Rewarming typically begins 24 hours after the initiation of cooling. Gradual rewarming at a rate of 0.25°C to 0.5°C (i.e., 0.45°F to 0.9°F) an hour over a 6 to 8 hour period helps prevent rapid changes in metabolic rate, electrolyte levels, and hemodynamics.⁶¹ Techniques include passive rewarming, resetting the temperature on commercial devices, and the application of heated-air blankets.

Discontinue analgesics, sedatives, and neuromuscular blockade during the rewarming phase. In landmark studies, Bernard stopped the neuromuscular blockade before 24 hours while Holzer maintained blockade for 32 hours.^{6,7} Other published protocols call for medications to be held when the core temperature reaches 35.5°C to 36.5°C (i.e., 95.9°F to 97.7°F). Treat shivering during the rewarming with a warm blanket and low-dose meperidine.⁶² Care must be taken to avoid hyperthermia/pyrexia (i.e., > 37.5°C or 99.5°F) by treating with antipyretics and active cooling for 72 hours postarrest. Hypotension and hyperkalemia commonly occur during rewarming.³ This requires close monitoring of the patient, the ECG tracings, and periodic laboratory analysis.³

TECHNIQUE FOR PEDIATRIC PATIENTS

Patients under the age of 18 were excluded from the landmark studies. The 2010 ILCOR guideline recommends that the induction of hypothermia should be considered for 12 to 24 hours in children

who remain comatose after resuscitation from a cardiac arrest.⁶³ There are now pediatric studies and reviews that have shown that there is mixed benefit to induced hypothermia.^{31,33,64-67} Neonates with perinatal asphyxia have been treated successfully with external cooling elements for 72 hours with impressive results.⁶⁸ Consult a Pediatric Intensivist and Pediatric Cardiologist prior to inducing hypothermia in a patient under the age of 18 years. The adverse events are different than in adults.⁶⁴

AFTERCARE

Consult an Intensivist and Cardiologist. Admit the patient to the appropriate Intensive Care Unit. Therapeutic hypothermia requires Intensive Care Unit admission for ventilator management as well as the continuous monitoring of core temperature, cardiac rhythm, blood pressure, and central venous pressure. Sedatives, paralytics, and orotracheal intubation are often required for patient comfort and shivering control.⁶⁹⁻⁷¹ Obtain laboratory analyses every 4 hours or as clinically indicated. Further bedside cardiac testing or cardiac catheterization laboratory intervention may be performed by a Cardiologist to help determine and treat the precipitating coronary artery disease. Consult a Neurologist for an electroencephalogram (EEG) and other neurologic testing to detect seizures and determine patient prognosis.⁷²

Begin standard Intensive Care Unit and post-cardiac arrest/acute coronary syndrome care in all patients after completion of therapeutic hypothermia. Consider the use of deep venous thrombosis prophylaxis with sequential compression devices, subcutaneous heparin, or subcutaneous low-molecular-weight heparin. Apply Lacrilube to the patient's eyes every 4 to 6 hours to prevent a corneal abrasion or corneal ulceration from dry corneas.⁶⁹ Consider the use of stress ulcer prophylaxis. Once the 24 hour therapeutic hypothermia period is completed, begin to rewarm the patient and wean any neuromuscular blockade and sedation. Extubation is determined and evaluated on a case-by-case basis.

The patient may not become responsive until 48 hours or later after rewarming.⁷³ Do not make early prognostic judgements regarding the patient.⁷⁴⁻⁷⁷ These are often wrong. Defer to the Intensive Care Unit teams all judgements regarding the patient outcome.

COMPLICATIONS

Emergency Physicians must be aware of several complications despite the proven safety and benefit of therapeutic hypothermia. Shivering during the induction phase increases core temperature and oxygen consumption. Low-dose buspirone, meperidine, opioids, and 4 gm of magnesium have been reported to lower the shivering threshold in awake hypothermic patients.^{62,78} Magnesium sulfate has the added benefits of improving cooling rates through vasodilatation while acting as an antiarrhythmic.⁷⁹ The use of orotracheal intubation and paralytics may be required to stop the shivering.

Pulmonary edema may occur with cooled IV fluid boluses. Arrhythmias may occur, especially with the use of endovascular cooling techniques. Other complications of bradycardia, decreased cardiac output, and increased systemic resistance are of unknown clinical significance. Hypothermic patients may be more susceptible to bacteremia and infection (e.g., pneumonia and sepsis).⁸⁰ The landmark studies showed only an insignificant trend toward increased sepsis. Post-cardiac arrest patients are at high risk of developing pneumonia in the first 48 hours, with aspiration being a key risk factor.³

A coagulopathy may occur due to changes in platelet function, clotting factor enzyme function, and fibrinolytic activity.^{81,82} Thrombolytics, heparin, and aspirin may be safely administered during induction when clinically indicated.^{16,83} A cold diuresis may

lead to electrolyte abnormalities including hypophosphatemia, hypomagnesemia, hypocalcemia, hypokalemia, or hyperkalemia. Hyperglycemia must be avoided to improve neurologic outcomes after cardiac arrest and in all critically ill patients. Increases in amylase and a transient rise in renal markers have been reported but are of unclear significance. Decreased core temperature often prolongs the duration of action of neuromuscular blockers (e.g., vecuronium) and sedatives (e.g., midazolam or propofol) by impairing metabolism.⁸⁴⁻⁸⁶ Rhabdomyolysis and subsequent renal failure are preventable by monitoring urine output and hydration.⁸⁷

The cooling devices themselves may be a source of complications. The endovascular catheter of internal cooling devices increases risk of infections and venous thrombosis similar to any central venous catheter (Chapter 63).⁵⁶ Right atrial thrombus has been reported with the use of internal cooling catheters.⁸⁸ External cooling devices may cause skin breakdown and tissue necrosis.⁵⁵

FUTURE CONSIDERATIONS

The use of esophageal cooling may be used in the future to induce and maintain therapeutic hypothermia.⁸⁹⁻⁹¹ The Esophageal Cooling Device (Advance Cooling Therapy, Chicago, IL) has been approved for use in the United States (Figure 225-6). It has been used for several years in Australia, Canada, and Europe. A single-use catheter attaches to an external cooling unit. The catheter is inserted into the esophagus like a nasogastric tube. It contains three lumens. Two of the lumens are for the circulation of cooling fluid. The third lumen allows gastric decompression and drainage.

SUMMARY

The staggering number of sudden cardiac deaths and the poor neurologic outcomes of survivors place an enormous burden on the health-care system. Two well-done landmark studies in 2002 clearly demonstrated improved survival and neurologic outcomes in comatose survivors of an out-of-hospital cardiac arrest with an initial rhythm of pulseless ventricular tachycardia or ventricular fibrillation treated with mild therapeutic hypothermia of 32°C to 34°C (i.e., 89.6°F to 93.2°F) for 12 to 24 hours. These results were incorporated into the recommendations from ILCOR and the AHA. These organizations recommend therapeutic hypothermia for comatose survivors of an out-of-hospital cardiac arrest with an initial rhythm of ventricular fibrillation or pulseless ventricular tachycardia. They also recommend no IV cold saline boluses and to cool to a targeted temperature between 32°C and 36°C (i.e., 89.6°F to 96.8°F) for

FIGURE 225-6. The Esophageal Cooling Device. (Photo courtesy of Advanced Cooling Therapy, Chicago, IL.)

at least 24 hours. No definite proven benefit has been shown for the use of target temperature management for the pediatric population. The induction of therapeutic hypothermia is a straightforward, inexpensive, safe, and effective procedure in any Emergency Department.

Hypothermic Patient Management

Jessen Schiebout

INTRODUCTION

The Centers for Disease Control and Prevention (CDC) reported 13,419 deaths from hypothermia in the United States between 2003 and 2013.¹ Approximately 67% of deaths were in males. Many think these figures underestimate the number of cases because standard thermometers do not measure low temperatures.^{1,2} Hypothermia is defined as a core body temperature below 35°C.² The normal physiologic thermoregulatory responses fail below this level and lead to an inability to generate enough heat to maintain bodily functions.^{3,4} Accidental hypothermia is further classified as primary or secondary.⁵ Primary accidental hypothermia occurs when a healthy individual's heat production is overcome by environmental factors.⁶⁻⁹ Secondary

accidental hypothermia occurs when predisposing factors lead to disruption of temperature homeostasis and increase the individual's susceptibility to lesser environmental stresses (e.g., drug intoxication, endocrine disorders, and trauma).³ Traumatic injury is a common example of an acquired condition associated with hypothermia.⁵

There are multiple reasons why trauma patients are at an increased risk for hypothermia.¹⁰ These include extended prehospital time, resuscitation with room temperature intravenous fluids, exposure to environmental factors, and physiologic characteristics of the trauma. Bleeding and hypoperfusion alter thermoregulation. Hypothermia is an independent risk factor for increased morbidity and mortality in trauma patients because of its association with coagulopathy and multiple organ failure.¹¹

Significant emphasis has been placed on the prevention of hypothermia as well as early recognition and correction of hypothermia in the prehospital setting. **Hypothermia can progress after the patient arrives in the Emergency Department.**¹² Many studies have demonstrated this phenomenon in traumatically injured patients.^{13–15} This recognition has prompted development of multidisciplinary approaches to maintaining normothermia as the patient moves through the hospital.¹⁶ **The importance of continuity and communication in dealing with hypothermia cannot be overstated.**

There are many other groups at risk for hypothermia. Infants lack a shivering response and exhibit a larger surface-to-volume ratio leading to rapid heat loss.^{17,18} Hypothermia is seen more frequently in southern states and during colder months.¹⁹ Malnourished or very thin individuals contain less insulating adipose tissue and less energy for metabolic heat generation.^{18,20–22} Endocrine disorders (e.g., hypothyroidism, hypoglycemia, diabetes, and adrenal insufficiency) lower metabolic heat production.^{17,20} Underlying infections, poverty, dementia, and conditions that impair peripheral vasoconstriction (e.g., burns and psoriasis) predispose to hypothermia. Drugs of abuse lead to diminished awareness of cold surroundings while others (e.g., opiates, clonidine, and tramadol) directly block the shivering mechanism.^{20,22,23}

Alcohol has been cited as the most common factor associated with hypothermia.¹⁸ Alcohol decreases shivering, causes hypoglycemia, and inhibits metabolic heat production.²⁴ Alcohol affects the hypothalamus. It changes the thermoregulatory set point and cold perception.^{18,25,26} Peripheral vasodilation increases heat loss and perceived comfort at cold temperatures and diminishes the drive to find warmer environments or clothing.^{24,26}

Hypothermia is common in the elderly population. They exhibit limited peripheral vasoconstriction and mobility.²⁷ Humans lose muscle mass during aging and this leads to decreased heat production from shivering. The elderly have impaired thermal sensation from frequently taken medications (e.g., beta-blockers or clonidine) that increase cold susceptibility.^{17–21,28,29}

Increased age and many other factors are associated with worse outcomes.³⁰ Serum lactate levels greater than 12.5 mmol/L or potassium levels greater than 10 to 12 mmol/L are considered terminal. Asystole as a presenting rhythm, drowning mechanism, and traumatic injury are all associated with worse outcomes.^{30–32} Patient's with prolonged hypothermia, secondary hypothermia, lower core temperatures, severe acidosis, concomitant infections, rhabdomyolysis, alcohol use, and increased comorbidities have a poorer prognosis.^{27,28,33,34}

ANATOMY AND PATHOPHYSIOLOGY

Heat is lost by conduction, convection, evaporation, and radiation. Conduction is the loss of heat energy through direct contact with a cooler entity (e.g., air, snow, water). The rate of heat loss

is proportional to the temperature gradient and size of the contact area. Convection is heat loss when liquids or gases flow over the body surface (e.g., Bair Hugger or wind). **Wet clothing can increase heat loss by convection and conduction up to 5 times and up to 25 times if a person is submerged in water.**³⁵ As wind speeds increase, heat loss by convection increases. Evaporation is heat loss through conversion of water to vapor (e.g., sweating). The rate of fluid evaporation and heat loss increases as humidity falls. Radiation is heat transfer from warmer to cooler objects via infrared rays and is proportional to the difference between body temperature and surrounding temperature. The hypothalamus detects falling blood temperature or cold signals from skin thermoreceptors, increases sympathetic drive, causes peripheral vasoconstriction, and causes shivering. The net effect is an increase in metabolic heat production to offset heat loss.³⁶

The Swiss Staging Model for hypothermia was invented to classify hypothermia based on clinical presentation and to predict core body temperature.³⁷ Shivering but lucid patients are classified as stage 1 and are predicted to be between 32°C and 35°C. Confused patients who are not shivering are predicted to be between 28°C and 32°C and meet stage 2 criteria. Unconscious patients with vital signs are predicted to be between 24°C and 28°C and are considered to be in stage 3. Stage 4 patients are predicted to be lower than 24°C and have no vital signs. This staging system is useful to classify patients but is not accurate in core temperature prediction.³⁷

Hypothermia is more commonly characterized as mild, moderate, and severe (**Table 226-1**).³⁸ Mild hypothermia is defined as a core temperature of 32°C to 35°C. Moderate hypothermia is defined as a core temperature of 28°C to 32°C. Severe hypothermia is defined as a core temperature of less than 28°C. The scale can be amended in the trauma patient to 34°C to 36°C for mild hypothermia, 32°C to 34°C for moderate hypothermia, and less than 32°C for severe hypothermia.

Mild hypothermia is associated with shivering, elevated heart rates, and elevated respiratory rates. The body increases heat production by increasing the shivering and increasing the metabolic rate. Peripheral vasoconstriction may result in acrocyanosis. Neurologic symptoms may include confusion, dysarthria, and impaired judgment.

Moderate hypothermia causes lethargy, hallucinations, loss of coordination, and diminished or dilated pupillary reflex. The patient stops complaining of “feeling cold” and the shiver mechanism is lost. Further temperature drop leads to peripheral autonomic nerve dysfunction and causes peripheral vasodilation. This creates a warm sensation and may explain the “paradoxical undressing” that is often seen.²⁰ Hyperreflexia is initially present. The muscles become stiff and tendon reflexes are lost as temperatures fall below 32°C.^{35,39} With every 1°C drop in core temperature, cerebral blood flow diminishes 6% to 7%.^{35,40,41} Cerebrovascular autoregulation is lost at 25°C.^{35,40,41} Brain wave changes are notable on an electroencephalogram (EEG) by 34°C and correlate with a cold narcosis. A cardiac standstill is seen at 29°C.^{22,35,42} Severe hypothermia is often associated with absent pupillary reflexes and coma.

Falling temperatures correlate with worsening bradycardia and decreased cardiac contractility.⁴² Reduced cardiac output may generate adequate blood flow due to decreased metabolic demands of the body.³¹ The heart rate typically falls by 30 to 40 bpm at 28°C. Lower heart rates may suggest other comorbidities (e.g., hypoglycemia or endocrine disorders).⁴⁰ The cardiac rhythm commonly converts from normal sinus to atrial fibrillation.⁴³

The patient is usually comatose by the time severe hypothermia is present, often with cardiopulmonary collapse. Ventricular irritability becomes evident and slight disturbances (e.g., bed transfers, orotracheal intubation, and nasogastric tube insertion) may lead to ventricular fibrillation. Intubation is frequently mentioned as a possible

TABLE 226-1 The Effects of Mild, Moderate, and Severe Hypothermia on Various Physiologic Systems

	Mild hypothermia (> 32°C)	Moderate hypothermia (28–32°C)	Severe hypothermia (< 28°C)
Cardiovascular system	Hypertension Sinus tachycardia	Atrial fibrillation Bradycardia Decreased P- and T-wave amplitude Hypotension Increased electrocardiogram intervals Osborne J waves	Asystole Heart blocks Pulseless electrical activity Severe bradycardia Ventricular fibrillation
Fluid and electrolytes	Cold diuresis	Hyperglycemia Hyperkalemia Lactic acidosis	Acute renal failure Hyperglycemia Hyperkalemia Lactic acidosis
Gastrointestinal (GI) system		GI bleeding Hepatic dysfunction Ileus Pancreatitis	GI bleeding Hepatic dysfunction Ileus Pancreatitis
Hematologic system		Decreased coagulation cascade Decreased platelets Hemoconcentration	Decreased coagulation cascade Decreased platelets Disseminated intravascular coagulation
Neurologic system	Ataxia Disorientation Dysarthria Hyperreflexia	Agitation Dilated pupils Hallucinations Hyporeflexia Stupor	Coma Nonreactive pupils
Respiratory system	Tachypnea	Aspiration Bradypnea Loss of cough reflex Shallow respirations	Apnea Acute respiratory distress syndrome Severe bradypnea
Thermoregulatory and musculoskeletal systems	Hypertonia Shivering	Loss of shivering Muscle rigidity	Pseudo-rigor mortis Rhabdomyolysis
Rewarming method	Passive Active external	Active external Noninvasive internal	Active external Invasive internal Noninvasive

inciting event for ventricular fibrillation. **The actual incidence is rare and intubation should not be withheld if clinically indicated.**^{40,44} Myocardial irritability results from associated hypoxia, acid-base disturbances, and increased sympathetic stimulation.³¹ Temperature gradients within the myocardium cause heterogeneous repolarization and fibrillation.⁴⁵ Ventricular fibrillation becomes refractory to conversion below 28°C. Asystole occurs at 20°C.

The characteristic electrocardiographic (ECG) finding of an Osborne J wave occurs at approximately 32°C (**Figure 226-1**). This is a positive deflection between the QRS and the ST segment typically seen in lateral or inferior chest leads. The Osborne wave is often only seen in one ECG lead.⁴⁶ The Osborne wave is produced by repolarization abnormalities correlating with temperature and pH.^{40,47,48} **The Osborne waves are not pathognomonic for hypothermia and can be seen in other conditions (e.g., brain injury, hypercalcemia, tricyclic overdoses, Brugada syndrome, and cardiac ischemia).**^{46,49} The PR, QT, and QRS intervals on the ECG lengthen as core temperature falls. The P wave amplitude decreases, heart blocks develop, and medications (e.g., atropine) become ineffective.^{40,46,48,49}

Oxygen consumption (VO_2) increases dramatically in mild hypothermia due to shivering. A core temperature decrease of 0.3°C is associated with a 7% increase in VO_2 . Temperature reductions between 0.3°C and 1.2°C have been reported to result in a 92% increase in VO_2 with proportional increases in minute ventilation.⁵⁰ The resultant increase in oxygen utilization may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress.⁵¹ However, temperatures below 33°C cause decreased VO_2 , tidal volume, and respiratory rates. Oxygen consumption and carbon dioxide production fall by 50% at 30°C. Every additional 1°C fall

in temperature causes a 6% drop in oxygen consumption.^{40,41} The ciliary action and the cough reflex are depressed below 33°C predisposing to atelectasis and aspiration.^{33,35,41} Moderate hypothermia leads to increased bronchial secretions and rewarming may cause pulmonary edema.^{22,33,41,44,52}

Metabolic problems associated with hypothermia include both hyperglycemia and hypoglycemia. Hyperglycemia results from elevated sympathetic drive and cold-induced pancreatic inhibition. Hypoglycemia is frequently seen and thought to be a predisposing factor instead of a cause for hypothermia.^{20,33} Hypothermia initially shunts blood from the periphery causing an elevation in blood pressure, an elevation of renal blood flow, and a cold diuresis.⁵³ Antidiuretic hormone release and distal tubule water reabsorption are directly affected as core temperature falls.^{41,43} This often results in blood urea nitrogen elevation, creatinine elevation, and electrolyte shifts.¹⁸ Further kidney injury may result from hypothermia-induced rhabdomyolysis.⁵⁴

Serum potassium is often slightly increased because of renal tubular dysfunction, acidosis, and the breakdown of liver glycogen. Hyperkalemia results from tissue necrosis at more advanced stages. It is recommended that uncorrected values be used to guide therapy due to the complexities of the acid-base balance associated with hypothermia when interpreting blood test results. These derangements are reversible with rewarming.

Multiple gastrointestinal organs are directly affected by hypothermia. Liver metabolism and the P450 system slow as temperature falls.⁵⁵ Gastrointestinal motility slows at temperatures below 34°C and an ileus may develop below 28°C. Gastrointestinal bleeding occurs from ulcer formation (i.e., Wischnevsky ulcers) and

FIGURE 226-1. The Osborne J wave associated with hypothermia is indicated by the arrows. This patient had a core temperature of 34°C.

pancreatitis.^{20,22,27,33,40,41} Gastrointestinal absorption is inhibited. Avoid medication administration orally or via nasogastric tube.

Coagulopathy is one of the most clinically significant metabolic derangements seen with hypothermia. Increased clotting times occur at core temperatures less than 35°C. Temperatures less than 32°C lead to severe platelet dysfunction.^{5,13} Cold platelets undergo morphologic changes affecting adherence and motility. Worsening hypothermia may lead to reversible platelet sequestration. Prostacyclin may become inhibited and promotes inappropriate platelet activation, disseminated intravascular coagulation (DIC), and thrombosis.^{35,40}

Lowering core temperature to 34°C decreases clotting factor activity up to 40% due to the direct effect on physiochemical activity.^{35,56} Cold-induced slowing of the enzymatic reaction rate of thromboxane synthetase results in decreased production of thromboxane A₂, a potent vasoconstrictor necessary for normal platelet aggregation.^{57,58} These derangements are reversible with rewarming. It is important to remember that clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. **The tests of coagulation reflect clotting factor deficiencies and are corrected for any potential effect of hypothermia on clotting factor function.**

Dehydration and increased vascular permeability often result in hemoconcentration. The hematocrit increases by 2% for every 1°C drop in temperature. Low hematocrit may suggest an underlying anemia and/or blood loss. Leukopenia may be seen due to splenic or hepatic sequestration.^{18,20,40}

INDICATIONS

Patients presenting with hypothermia must be identified and treated (Table 226-2). **Hypothermia should be easily identified since a temperature is obtained in all patients presenting to the**

Emergency Department. Patients may develop hypothermia while in the Emergency Department. **Cover all patients with warm sheets or blankets as soon as their initial evaluation and any necessary procedures are completed.**

CONTRAINDICATIONS

There are few contraindications for treating hypothermia. **Serum potassium greater than 10 to 12 mmol/L and lactates greater than 12.5 mmol/L suggest futile resuscitative efforts.**^{30-33,53,59-62} Those

with do not resuscitate (DNR) orders should not receive cardiopulmonary resuscitation (CPR) if they arrest. Many suggest withholding transport and care if rigor mortis is present; however, severe hypothermia causes muscle stiffness making this unreliable. Good neurologic outcomes have been demonstrated in prolonged extraction and intermittent CPR for multiple hours.

Warming faster usually produces better outcomes.⁶¹ Hypothermic brain injury patients warmed at slower rates did not show benefit and hypothermic patients with cardiac arrest do not benefit from additional therapeutic hypothermia.⁶² Patients have worse neurologic recovery if temperature correction overshoots.⁶³ Stop active rewarming at 33°C to 35°C.^{20,62} There are circumstances where induced therapeutic hypothermia may be of benefit (Chapter 225).⁶⁴⁻⁶⁷

SPECIAL RESUSCITATION CONSIDERATIONS

All patients with hypothermia are identified by measurement of core body temperature on admission. Close subsequent monitoring is necessary and required. Poor peripheral perfusion may result in difficulty assessing the pulse and blood pressure. This makes the use of Doppler ultrasound (US) necessary. Cutaneous probes for temperature and pulse oximetry have difficulty picking up signals in hypothermic patients. Oral and auricular temperature probes are often inaccurate. Consider using bladder, esophageal, or rectal temperature probes. Esophageal temperature probes will be inaccurate if using heated oxygen. Rectal or bladder temperature probes are less accurate if peritoneal or bladder lavage is used. Place rectal temporal probes at a depth of 15 cm to obtain an accurate core temperature measurement.⁶⁸

Airway management is often required in patients with moderate and severe hypothermia. Standard orotracheal intubation may be difficult due to jaw muscle rigidity. Neuromuscular blocking agents are ineffective with core body temperatures less than 30°C and succinylcholine may acutely worsen acute hyperkalemia.^{33,53,68} The use of topical vasoconstricting agents, smaller endotracheal tubes, and blind nasotracheal intubation has been suggested.³³ Fiberoptic-guided orotracheal intubation can be utilized if available. Periodically monitor the endotracheal cuff pressure as it may increase with patient rewarming. Chest wall elasticity and pulmonary compliance diminish in hypothermia and ventilatory pressures increase.¹⁸ Ventilate patients at 8 to 12 breaths per minute to avoid respiratory alkalosis.³⁵

Management of the circulatory system with moderate to severe hypothermia often requires fluid resuscitation as these patients are volume depleted. Dextrose-containing fluids are contraindicated because the warmed solution will caramelize. Ringer's solution is not recommended due to decreased hepatic metabolism of lactate when hypothermic. **The heart is susceptible to arrhythmias. Take special care when transferring patients on beds or performing procedures. Avoid transthoracic central venous catheters and pulmonary artery catheters until rewarming has been achieved.** Use peripheral intravenous catheters or a femoral central venous line as the guidewire does not reach the heart.

Treat nonperfusing cardiac rhythms using Advanced Cardiac Life Support (ACLS) guidelines. The presence of bradycardia, atrial fibrillation, and other dysrhythmias that do not reduce perfusion do not require pharmacologic support and these will reverse with rewarming. The pulse is clinically difficult to detect in severe hypothermia due to decreased cardiac rate, decreased cardiac contractility, and severe vasoconstriction. Perform bedside US to look for cardiac activity, especially if the presenting rhythm is pulseless electrical activity. Do not initiate CPR unless no central pulse is palpable for 1 minute or pulses are noted to disappear.

Hold CPR unless there is true cardiac arrest due to lower metabolic demands and predisposition of ventricular fibrillation.^{18,44} **Defibrillation at core body temperatures less than 30°C to 32°C may not be effective. Up to three defibrillations may be given. Hold further defibrillation until a core temperature of 30°C has been achieved. Continue resuscitative efforts in conjunction with rewarming.** Those with severe hypothermia may require more forceful compressions due to increased stiffness of cardiac and chest wall tissues.^{18,31,33,35,44,69} Attempt to pace the heart transcutaneously if needed.⁷⁰

Resuscitation drugs are often ineffective at core body temperatures below 30°C. Lidocaine, verapamil, diltiazem, and neuromuscular blocking agents may have decreased efficacy. Procainamide has been suggested to increase ventricular fibrillation.^{35,69} Hypothermia increases the duration of action for rocuronium and vecuronium.⁷¹⁻⁷⁴ **Hypothermia elevates serum concentrations of propofol, fentanyl, and midazolam.**^{71,75,76} The overall effect on opiate administration is unclear because the opiate receptor exhibits diminished responsiveness.⁷⁷ Epinephrine metabolism slows and may accumulate to toxic levels if administered at standard ACLS doses.³¹ **It is recommended that medications be administered at one-half the normal dose during the resuscitation of a moderately or severely hypothermic patient to avoid drug toxicity.** Avoid vasopressors due to their potential to cause arrhythmias.³⁵ Repeat the resuscitation cycle with every increase in core body temperature of 1°C to 2°C until normothermia is achieved.⁶⁹ **Patients should not be pronounced dead until they are warm (i.e., greater than 32°C) and dead.** Table 226-3 lists pertinent tests in hypothermic patients.

FLUID MANAGEMENT

The administration of fluids or blood products can exacerbate hypothermia. Infusion of 1 L of crystalloid solution at room temperature (i.e., 21°C) results in a 0.3°C decrease in core body temperature.⁵ **Take active measures to prevent hypothermia when patients are receiving large volumes of resuscitation fluid. This is even more important in patients receiving blood products that are kept at 4.0°C.** Transfusion of 1 L of blood products leads to a decrease in core body temperature of 0.54°C.⁵ **A normothermic patient can be rendered hypothermic quickly when subjected to an aggressive fluid resuscitation.**

One of the mainstays in the hypothermia prevention during resuscitation is the use of fluid warmers to infuse intravenous fluids. Conventional fluid warmers use a coil or sleeve system in a water bath and pose problems at both slow and rapid infusion rates.⁷⁸ Slow infusion rates allow time for the fluid to cool in the

FIGURE 226-2. Examples of warming devices. **A.** Smiths Medical Level 1 H-1200. **B.** Hotline Level 1. **C.** TheraCor 1200 (Smisson-Cartledge Biomedical, Macon, GA.)

tubing between the warmer and the patient. Fast infusion rates leave inadequate time to warm the intravenous fluid.

These problems have been addressed with devices that are useful in the Emergency Department (**Figure 226-2**). They warm infused fluid to a temperature of 40°C. The first uses a jacket in which circulating warmed fluid covers the entire length of the intravenous tubing from the warming device to the patient (Hotline, Smiths Medical, Norwell, MA). This device is more effective than conventional fluid warmers at flow rates between 50 and 6000 mL/hr.⁷⁸ The second device uses an inline heating unit that warms the fluid rapidly and allows for substantially higher infusion rates (ThermaCore 1200, Smisson-Cartledge Biosystems, Macon, GA). This device can infuse crystalloid solutions or blood products at rates up to 1200 mL/min and is extremely useful in the resuscitation of patients in severe hemorrhagic shock. Similar devices are available from a variety of manufacturers. **Use these devices to administer intravenous fluid to hypothermic patients or to those at risk for developing hypothermia.** These devices may be used in conjunction with the techniques described below.

PASSIVE EXTERNAL REWARMING

Perform passive external warming on all patients who are mildly hypothermic or who have normal body temperatures and are undressed.^{79,80} Approximately 90% of heat loss occurs through the skin.^{33,53,71} Cover the patient with warm sheets and blankets as soon as they have been examined and any necessary procedures have been performed.

TECHNIQUES

Remove any wet and/or cold clothing. Dry the patient before applying blankets (Figure 226-3). Blankets and sheets may be kept in a blanket warmer as insulating material cooler than the patient (i.e., room temperature) will extract heat. **Prevent secondary injury**

FIGURE 226-3. Passive external rewarming. Remove any wet and/or cold clothes. Cover the patient with warm blankets.

to the patient from blankets and sheets that are too hot. There is no reason for the blankets to be any warmer than normal body temperature for passive external rewarming.

ASSESSMENT

An otherwise healthy and normal patient will increase their core body temperature by 0.5°C/hr to 2.0°C/hr with passive external rewarming. The body attempts to regain normothermia by increasing its metabolic rate. The patient may manifest evidence of increased cardiopulmonary stress and lactic acidosis during this time.⁵

COMPLICATIONS

Complications occur if attempts are made to place inappropriately heated objects directly on the patient. **Under no circumstances should heated intravenous fluid bags be placed in prolonged contact with the skin.** This may result in thermal injuries ranging from superficial blistering to full-thickness burns. Blankets and sheets that are too warm will also cause damage to the skin.

SUMMARY

Use passive external rewarming as a sole agent in otherwise healthy patients with normothermia who are undressed, patients with mild hypothermia, and as an adjunct to more aggressive rewarming techniques. **Always be aware of the possibility of a patient developing hypothermia during their Emergency Department stay.**

ACTIVE EXTERNAL REWARMING

INDICATIONS

Perform these maneuvers as sole therapy for patients with mild hypothermia, on awake and otherwise stable patients with moderate hypothermia, and in conjunction with more aggressive rewarming techniques.

CONTRAINDICATIONS

Do not use active external rewarming as the sole therapy for patients with moderate hypothermia who have altered mental status or hemodynamic instability. Active external rewarming is contraindicated as the sole therapy for patients with severe hypothermia. **There is no significant difference in the rates of rewarming between the different devices used for external rewarming. The use of radiant heaters and heating packs is not currently recommended due to the risk of potential complications and limited efficacy.**^{39,81}

EQUIPMENT

- Warm blankets
- Forced air rewarming blankets (Figures 226-4A, 226-4B, and 226-4C)
- Fluid circulating rewarming blankets (Figure 226-4D)
- Water bath and associated supplies

TECHNIQUE

Examine the patient. Determine if the patient is a candidate for active external rewarming. Place a forced air rewarming blanket or a fluid circulating rewarming blanket on the patient (Figure 226-5). **Do not place these blankets, particularly the fluid circulating ones, underneath the patient.** Placing the blanket under the patient may

lead to excessive thermal transfer to areas with decreased blood flow due to pressure and prolonged time of contact. A thin sheet may be placed between a fluid circulating blanket and the skin. This is not necessary with forced air blankets. Warmed blankets and sheets may be placed over the warming blankets.

Active external rewarming can be accomplished by immersion of the patient in a warm water bath (Figure 226-6). This technique is easy, effective, and simple. Immersion therapy in the Emergency Department is not practical. The equipment is bulky, not portable, and occupies a large fixed space. Monitoring leads (i.e., electrocardiography and pulse oximetry) will not adhere to wet skin and water submersion precludes care for concomitant medical issues.

ASSESSMENT

Care must be taken to reassess any wounds for recurrent bleeding, any catheters or monitors for placement, and any pressure areas that might be in prolonged contact with the heating elements as the patient is covered with the warming device. **Check the air source connection to the blanket to make sure that the hot air is not blowing directly onto the patient.** A directed flow of hot air onto the patient under the blanket may lead to thermal injury.

COMPLICATIONS

Thermal injuries are associated with active external rewarming. They result from improper use of the devices. Maintain vigilance regarding prevention of a focused delivery of heat to a region of skin, particularly one poorly perfused, to essentially eliminate these burns.

Afterdrop refers to a decrease in core temperature that occurs 15 to 20 minutes after active external rewarming begins.⁶⁹ This is thought to be due to vasodilatation of the peripheral tissues as they rewarm and a subsequent washout of cooler peripheral blood back to the central areas. Peripheral vasodilatation can lead to hypotension if fluid resuscitation is inadequate or the patient has cardiovascular compromise. Afterdrop can be attenuated by the concomitant use of core rewarming techniques.

SUMMARY

Active external rewarming is useful in treating moderately hypothermic patients who are awake and alert. Warming rates of 1.0°C/hr to 2.5°C/hr have been reported.³⁵ Frequent monitoring for potential thermal injuries is required to prevent secondary injury. Monitoring is easier when the patient is a cooperative partner who can participate in the process. Active external rewarming, like passive external rewarming, is often used in conjunction with more aggressive techniques or core rewarming. The problem of afterdrop is lessened when active external rewarming is used in conjunction with core warming techniques.

AIRWAY REWARMING

Airway rewarming with warmed and humidified oxygen is safe and easily achieved (Figure 226-7). It can be applied to any hypothermic patient. However, airway rewarming is never used as a sole means of rewarming.

INDICATIONS

The technique of airway rewarming may be used in any patient with hypothermia and in conjunction with other techniques. Any patient receiving supplementary oxygen can receive warmed and humidified oxygen. Its efficacy via endotracheal tube is greater than via mask or nasal prongs.

(Photo courtesy of Augustine Temperature Management, Eden Prairie, MN.) **D.** Stryker Altrix fluid circulating warmer. (Photo courtesy of Stryker Medical, Portage, MD.)

CONTRAINDICATIONS

There are no contraindications to airway rewarming. The more severely hypothermic patient will often need their airway controlled by orotracheal intubation due to a depressed level of consciousness. **Intubation for the sole purpose of airway rewarming is contraindicated.**

EQUIPMENT

- Nasal cannula
- Face mask
- Endotracheal tubes
- Humidifier tank

FIGURE 226-5. Active external rewarming with a forced air heating blanket.

- Heating circuit
- Oxygen source

TECHNIQUES

Consult the Emergency Department Respiratory Therapist. They will gather, set up, administer, and monitor the required equipment (**Figure 226-7**). Connect the humidifier tank and heating circuit in line with the oxygen source. Humidify and warm the inhaled oxygen to 40°C to 45°C. A rewarming rate of 1.0°C/hr to 2.5°C/hr has been reported.³⁵ **Avoid reliance on esophageal temperature probes as these may give falsely elevated readings.**

SUMMARY

Airway rewarming can be applied to any hypothermic patient. The oxygen must be humidified to prevent fluid loss from evaporation.

GASTRIC AND BLADDER LAVAGE

These techniques are based on techniques familiar to Emergency Physicians, are minimally invasive, and can be readily performed with minimal interruption of continued resuscitative efforts.⁸²

FIGURE 226-6. Active external rewarming with a water bath.

FIGURE 226-7. Airway rewarming equipment with humidified and warmed oxygen. The Opti-Flow cannula and humidifier. (Photo courtesy of Fisher and Paykel Healthcare Ltd., Irvine, CA.)

INDICATIONS

These techniques are usually reserved for patients with severe hypothermia. They are rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available. Gastric lavage can be used for decontamination of stomach contents in the patient who overdoses and is hypothermic.

CONTRAINDICATIONS

The only contraindications to these techniques are the contraindications to the placement of a urethral catheter (Chapter 173) and a nasogastric tube (Chapter 75). Do not perform gastric lavage concurrently with cardiac compressions. Gastric and bladder lavage are of limited value in the management of the hypothermic patient. They are generally bypassed in favor of peritoneal lavage, pleural lavage, and extracorporeal warming.

EQUIPMENT

- Warmed (40°C) intravenous fluid, normal saline or Ringer's lactate
- 60 mL catheter-tip syringe
- Urethral catheterization supplies (Chapter 173)
- Nasogastric intubation supplies (Chapter 75)

TECHNIQUES

Place a Foley catheter (Chapter 173) and/or nasogastric tube (Chapter 75). Confirm their proper placement. Instill sterile saline or Ringer's lactate warmed to 40°C. Inject 60 mL aliquots into the tubes using the catheter-tipped syringe. Instill a total of 300 to 400 mL into the stomach and 200 to 250 mL into the bladder. **Do not over-distend the respective organ.** Gastric overdistention can result in rupture or aspiration. Bladder overdistention can result in rupture and extravasation of fluid. Clamp the Foley catheter and nasogastric tube. Allow the fluid to dwell within the organ for 5 to 10 minutes. Remove the fluid by gravity drainage from the bladder or suction from the stomach. Repeat the process as necessary until the core body temperature increases. Bladder and gastric lavage each add 0.5°C/hr to 1°C/hr.⁶⁸

COMPLICATIONS

Gastric lavage may be complicated by perforation of the stomach by the nasogastric tube or overdistention. Aspiration is a potential complication with gastric lavage. Nasogastric tube placement may provoke arrhythmias in severe hypothermia. These techniques make esophageal and rectal temperatures less accurate. Refer to Chapters 75 and 77 for a more complete discussion of the complications associated with nasogastric intubation and gastric lavage, respectively.

Bladder irrigation is safe if the bladder is not overdistended. The small surface area of the bladder makes it an inefficient means of rewarming. Refer to Chapter 173 for a more complete discussion of the complications associated with urethral catheterization. Use normal saline as sterile water can result in significant volume and electrolyte shifts.

SUMMARY

Perform gastric or bladder irrigation if other types of body cavity rewarming are contraindicated. These techniques are easily initiated using standard equipment in an Emergency Department. These organs have relatively small surface areas which makes these techniques inefficient. Overdistention of the bladder or stomach can result in serious complications.

PERITONEAL LAVAGE

This technique is invasive, is based on techniques familiar to Emergency Physicians, and can be readily performed with minimal interruption of resuscitative efforts.

INDICATIONS

This technique is usually reserved for patients with severe hypothermia. It is rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available.

CONTRAINDICATIONS

Suspicion of injury to a hollow viscus is a contraindication to this technique. The presence of a previous laparotomy scar is a strong relative contraindication. The use of an open peritoneal lavage technique does not work well with the continuous infusion of fluid required for this procedure. Other contraindications are those associated with performing a diagnostic peritoneal lavage (Chapter 84).

EQUIPMENT

- Warm (40°C) intravenous fluid, normal saline or Ringer's lactate
- Warm (40°C) peritoneal dialysis fluid

- Fluid infuser device, optional
- Peritoneal lavage kits
- Peritoneal lavage supplies (Chapter 84)
- Nasogastric tube supplies (Chapter 75)
- Foley catheter supplies (Chapter 173)

A commercially available, disposable, single patient use peritoneal lavage kit is available from numerous manufacturers. The kit includes all the material required to perform a closed or semi-open diagnostic peritoneal lavage except lavage fluid. An example is the Arrow kit (Arrow International, Reading, PA). It contains 10% povidone iodine or chlorhexidine swabs, gauze squares, fenestrated drape, tubing for the administration of intravenous fluid, 1% lidocaine, 5 mL syringes, 22 and 25 gauge needles, an 18 gauge × 2.5 inch introducer needle, an 0.89 mm × 45 cm J-tipped guidewire, an 8 French lavage catheter, and a #11 scalpel blade on a handle. Refer to Chapter 84 for a more complete list of equipment.

TECHNIQUE

Prepare the patient by placing a nasogastric tube (Chapter 75) and a Foley catheter (Chapter 173). Place two peritoneal lavage catheters (Chapter 84), one supraumbilical and one infraumbilical (**Figure 226-8**). Confirm the position of the peritoneal catheters. Clamp the infraumbilical peritoneal catheter. Infuse warm (40°C) intravenous fluid or peritoneal dialysis fluid through the supraumbilical peritoneal catheter using the Level 1 infuser or a fluid warmer. The use of dialysate has the added benefit of potentially correcting some electrolyte abnormalities.^{35,69} The fluid may be infused manually but this technique is much less efficient. Infuse 1 to 2 L of fluid. Allow the fluid to bathe the peritoneal cavity for 10 minutes. Remove the clamp on the infraumbilical peritoneal catheter and allow the fluid to drain from the peritoneal cavity. Repeat the procedure. Up to 10 L/hr of fluid may be infused in this fashion.³⁵ An alternative technique is to allow the fluid to flow at a moderate rate continuously through the supraumbilical peritoneal catheter, into the peritoneal cavity, and out the infraumbilical peritoneal catheter. This can

FIGURE 226-8. Active core rewarming with peritoneal lavage.

FIGURE 226-9. The Veratherm Portable Hypothermic Perfusion System.

be performed manually or with a commercial device developed for this purpose (Veratherm Portable Hyperthermic Perfusion System, Thermal Therapeutic Systems Inc., Pittsburg, PA) (**Figure 226-9**).

COMPLICATIONS

The potential complications are primarily associated with the placement of the peritoneal lavage catheter (Chapter 84). The infusion and removal of the fluid are safe. Avoid using highly hyperosmolar peritoneal dialysates in patients with persistent hypovolemia or with a questionable perfusion status as this may worsen existing hypovolemia. Do not use sterile water as it can result in significant volume and electrolyte shifts.

SUMMARY

Peritoneal lavage is the most widely recognized means of body cavity lavage. This is due in part to the familiarity with the diagnostic peritoneal lavage procedure. It has the advantage of being able to be performed concurrently with chest compressions and other resuscitative efforts. This technique can raise the core body temperature by 1°C/hr to 3°C/hr.

PLEURAL LAVAGE

This technique is invasive, is based on techniques familiar to most Emergency Physicians, and can be readily performed with minimal interruption of resuscitative efforts. Pleural lavage can be performed closed (i.e., tube thoracostomy) or open (i.e., a thoracotomy).

INDICATIONS

This technique is usually reserved for patients with severe hypothermia. It is rarely used in stable patients and generally reserved for situations where extracorporeal warming is not available. Pleural lavage is superior to gastric and bladder lavage.⁶³

CONTRAINDICATIONS

The presence of a pneumothorax and/or hemothorax is the only contraindication to pleural lavage. This procedure is difficult when performed in conjunction with chest compressions.

EQUIPMENT

- Tube thoracostomy supplies (Chapter 51)
- Warm (40°C) intravenous fluid, normal saline or Ringer's lactate

- Warm (40°C) peritoneal dialysate
- Fluid infuser device, optional

TECHNIQUE

Place two chest tubes (Chapter 51) into the same pleural space, either the left or the right side, to perform closed pleural lavage (**Figure 226-10**). The left side is preferred by those who believe that the heart, aorta, and blood within the aorta will be warmed quicker than with right-sided chest tubes. Place one tube anteriorly in the second or third intercostal space at the midclavicular line (**Figure 226-10**). Place the other tube posteriorly in the fifth or sixth intercostal space at the posterior axillary line (**Figure 226-10**). Secure the tubes to the chest wall with suture and tape. Attach the fluid infuser to the anterior chest tube using a Christmas tree adapter. Apply a pleural drainage device to the posterior chest tube in the usual fashion. Infuse warm (40°C) fluid via the fluid infuser device at a rate of 180 to 550 mL/min.⁶⁹ Allow the fluid to exit into the pleural drainage device. The fluid will flow into the anterior chest tube, bathe the structures in the hemithorax (i.e., great vessels, heart, lung, and mediastinum), and exit via the posterior chest tube. This can be performed manually or with a commercial device developed for this purpose (Veratherm Portable Hyperthermic Perfusion System, Thermal Therapeutic Systems Inc., Pittsburg, PA) (**Figure 226-9**).

Pleural lavage may be performed using an open technique (**Figure 226-11**). This technique is used when a thoracotomy (Chapter 54) is indicated for other purposes (e.g., penetrating trauma or to perform open cardiac massage). **Do not use this technique for the sole purpose of rewarming if other less invasive or extracorporeal techniques are available.** The advantage of open pleural lavage is that it allows direct cardiac rewarming and open cardiac massage.

COMPLICATIONS

The complications are primarily associated with the placement of the chest tube (Chapter 51) or the thoracotomy (Chapter 54). Maintain free drainage of the irrigation fluid to avoid increasing the intrathoracic pressure.

FIGURE 226-10. Active core rewarming with closed pleural lavage.

FIGURE 226-11. Active core rewarming with open pleural lavage.

SUMMARY

Closed pleural lavage is an effective means of rewarming. It can increase the core body temperature by 1°C/hr to 5°C/hr. It is very similar in efficacy to peritoneal lavage. Chest tube placement is slightly more challenging than placement of a peritoneal lavage catheter. Free drainage is usually easier to achieve and maintain with a chest tube than with a peritoneal lavage catheter. The two techniques may be employed simultaneously and carried out in conjunction with other resuscitative measures.

EXTRACORPOREAL REWARMING

Extracorporeal rewarming is the most aggressive, effective, and efficient technique to correct severe hypothermia (Chapter 73). It has been shown to improve outcomes in those with hypothermic cardiopulmonary arrest and there is growing evidence supporting its use in patients with severe hypothermia.^{83,84} It is suggested that Emergency Medical Services transport severely hypothermic patients to centers capable of these procedures even if transportation times are increased.^{31,59,68}

Extracorporeal rewarming includes the use of hemodialysis, arteriovenous rewarming, venovenous rewarming, continuous venovenous hemofiltration, cardiopulmonary bypass, and extracorporeal membrane oxygenation. The choice between the techniques is made based on availability of resources and the Emergency Physician's familiarity with each technique. Cardiopulmonary bypass is discussed but should not be performed by anyone who is not a Surgeon familiar with the procedure.

HEMODIALYSIS

Hemodialysis is readily available in most institutions. It requires the placement of a specialized double-lumen central venous line. The only contraindications to hemodialysis are those associated with central venous line placement (Chapter 63) and hemodialysis. An advantage of hemodialysis is that associated drug toxicity or significant electrolyte abnormalities can be simultaneously managed as the patient is being rewarmed.^{85,86}

EQUIPMENT

- Central line supplies (Chapter 63)
- Dual-lumen percutaneous hemodialysis (e.g., Quinton or Mahurkar) catheter
- Dialysis machine

- Dialysis nurse or technician
- Warmed (40°C) dialysis fluid

TECHNIQUE

Place a double-lumen central venous hemodialysis catheter into a femoral vein (Chapter 63). The catheter may be placed into a subclavian vein if femoral vein access is contraindicated. Femoral vein placement decreases the risk of inducing an arrhythmia with the guidewire.³⁵ There is a tendency to have fewer problems related to the positioning of the catheter and achieving appropriate flow rates with femoral catheters. Instruct the hemodialysis technician to set the temperature control on the dialysis machine to deliver a blood temperature of 40°C. Attach the dialysis machine tubing to the lumens of the catheter. Hemodialysis warms patients at 2°C/hr to 3°C/hr.⁶⁸

COMPLICATIONS

The potential complications are primarily associated with the placement of the central venous line (Chapter 63). The hemodynamic status of hypotensive patients may become worse upon initiation of hemodialysis but this technique has been successfully used on hypothermic patients.³⁵

SUMMARY

Hemodialysis is available at most institutions and is effective in rewarming a patient.^{85,86} The limitations of this technique include the need to have a dialysis technician or nurse available, the time required to obtain on-call personnel, and the time required to set up the equipment. Hemodialysis is a viable option for the rewarming of a hypothermic patient when other forms of extracorporeal warming are not available.

ARTERIOVENOUS REWARMING

This technique was initially described in 1992.^{87,88} The authors described placing one large-bore catheter in the femoral artery and another in a central vein (i.e., femoral, internal jugular, or subclavian). This method allows for rewarming in the Emergency Department without the need for specialized equipment (e.g., dialysis or bypass machine) or heparin administration (Figure 226-12).⁸⁹

CONTRAINDICATIONS

This method requires the patient's own blood pressure to circulate blood through the warming system. Hypotension or cardiac arrest makes this method ineffective. Known occlusive arterial disease, particularly in the iliofemoral region, is a relative contraindication.

EQUIPMENT

- Central line supplies (Chapter 63)
- Two 8.5 French introducer catheters
- Two 10 French single-lumen arteriovenous hemofiltration catheters
- Fluid warmer
- Luer-lock adapter, male-to-male
- Warmed (40°C) saline

TECHNIQUE

Place two catheters, one in the femoral artery and one in a central vein (Chapter 63). The placement of the arterial catheter is like that of the venous catheter.

FIGURE 226-12. Arteriovenous rewarming.

The tubing for the Level 1 rapid infuser consists of two intravenous spike-tipped lengths that come together in a “Y.” The “Y” runs to a countercurrent warming chamber and then to the patient. Cut off the spike tip from one of the limbs of the “Y” and attach the male-to-male Luer-lock adapter. An additional length of wide-bore intravenous tubing may be needed to bridge the distance between the arterial catheter and the fluid-warmer tubing. Connect this limb to the arterial catheter. Connect the other arm of the “Y” to a bag of intravenous fluid with the roller clamp closed.

Allow the system to prime with blood under the patient’s arterial pressure. Connect the primed distal end of the tubing to the central venous catheter. The blood will travel via the arterial catheter to the extracorporeal circuit and through the proximal limb of the tubing to the warming chamber of the Level 1 infuser, through the heating elements to the distal tubing, and back to the patient via the venous catheter (Figure 226-12).

The driving force in this circuit is the patient’s systemic blood pressure. Low-flow states will limit the efficacy of the system. A pressure infusion of intravenous fluid via the other limb of the “Y” augments flow. This fluid will be warmed as it reaches the patient, since this other limb of the “Y” is proximal to the warming element. Systemic anticoagulation is not required as the tubing for the Level 1 infuser is heparin-bonded. Arteriovenous rewarming is faster and more efficient than venovenous rewarming.⁹⁰

COMPLICATIONS

The complications outlined in the initial description of the procedure include the inability to achieve vascular access, a small hematoma at the arterial puncture site, and ischemia of the limb distal to the arterial catheter.⁸⁷ Refer to Chapters 63 and 72 for a full description of the complications that may arise in placing a central venous catheter and an arterial catheter, respectively.

SUMMARY

Arteriovenous rewarming is an innovative means by which severely hypothermic patients may be rapidly rewarmed without the resources of a dialysis or a bypass pump technician. This mechanism utilizes the patient’s own blood pressure gradients and can warm efficiently by approximately 3°C/hr to 4°C/hr.⁵³

VENOVENOUS REWARMING

This technique is rarely utilized by Emergency Physicians due to the lack of a venous roller pump and inexperience with this piece of equipment. The technique is briefly described for the sake of completeness. The venovenous technique has two main advantages over arteriovenous rewarming.⁹¹ First is the lack of arterial cannulation and its potential for limb ischemia. The second is not relying on systemic blood pressure to drive the system. Flow may be independently determined and delivered by the roller pump. This may be particularly important in the severely hypothermic patient who presents in full cardiorespiratory arrest. The primary disadvantage of this technique is the requirement of expertise in using the roller pump, although advances in design may obviate this in the future.

CONTRAINDICATIONS

Persons not familiar with the function and operation of a venous roller pump should not attempt this technique.

EQUIPMENT

- Central line supplies (Chapter 63)
- Two 8.5 French introducer catheters
- Two 10 French single-lumen arteriovenous hemofiltration catheters
- Fluid warmer
- Luer-lock adapter, male-to-male
- Venous roller pump
- Warmed (40°C) saline

TECHNIQUE

The setup for this technique is like that for arteriovenous rewarming.⁹¹ Place two central venous catheters (Chapter 63), one in the femoral vein and one in another central vein. Alternatively, place a dual-lumen hemodialysis catheter.⁹² Ensure that the “outflow” port of the hemodialysis catheter is upstream and that the “inflow” port is downstream. This helps to reduce the amount of warmed fluid returning from the circuit that is immediately withdrawn by the roller pump. Place the venous roller pump in line with this circuit between the patient and the warming elements. Adjust the flow rate within the tolerances of the device.

COMPLICATIONS

The primary complication associated with use of venous roller pumps is an air embolus. This usually happens when the roller pump is operated by a person unfamiliar with it. Recent advancements in roller pump technology have made their operation simpler and safer. Refer to Chapter 63 for a complete description of the complications that may arise due to the placement of a central venous catheter.

SUMMARY

Venovenous rewarming is one step away from cardiopulmonary bypass. Its use in the Emergency Department is limited due to lack of equipment availability and familiarity. It is a viable option if a

roller pump is available as well as a Physician familiar with this procedure. Warming rates of 4°C/hr to 10°C/hr have been noted.^{68,91}

CONTINUOUS VENOVENOUS HEMOFILTRATION

Continuous venovenous hemofiltration (CVVH) machines have become more widely available. This is an attractive means of rewarming. The use of CVVH machines has largely replaced the venovenous rewarming technique. This technique has two main advantages over arteriovenous rewarming. First is the lack of arterial cannulation with its potential for limb ischemia. The second is not relying on systemic blood pressure to drive the system. The use of CVVH in the management of moderate-to-severe accidental hypothermia has been shown to be rapid, safe, and effective.^{88,93}

CONTRAINDICATIONS

Persons not familiar with the function and operation of a CVVH machine should not attempt this technique.

EQUIPMENT

- Central line supplies (Chapter 63)
- Dual-lumen percutaneous hemodialysis (e.g., Quinton or Mahurkar) catheter
- CVVH dialysis machine
- Dialysis nurse, dialysis technician, or trained Intensive Care Unit nurse
- Warmed (40°C) dialysis fluid

TECHNIQUE

Rewarming with CVVH utilizes a single intravenously inserted, dual-lumen catheter placed in a central vein and connected to the CVVH dialysis machine. Some CVVH dialysis machines have a built-in thermostat allowing for temperature control while others depend on circulating already warmed dialysis fluid bags. Passive and/or active external rewarming maneuvers should be used in conjunction to the CVVH technique. Continuously monitor cardiopulmonary monitoring and core body temperature.

COMPLICATIONS

Recent advancements in CVVH technology have made their operation simpler and safer in terms of the prior concern over an air embolism. Their use should be restricted to individuals familiar with the operation of these devices. Refer to Chapter 63 for a complete description of the complications that may arise due to the placement of a central venous catheter.

SUMMARY

CVVH is one step away from cardiopulmonary bypass. Its use in the Emergency Department is limited due to lack of equipment availability and familiarity. It is a viable option if the equipment is available as well as a Physician familiar with this procedure. It has a reported warming rate of 1.5°C/hr to 3°C/hr.^{68,83,94}

CARDIOPULMONARY BYPASS

Discussion of this technique is limited to some basic properties of rewarming with cardiopulmonary bypass. This technique should not be attempted by anyone who does not regularly use bypass modalities and without the support of an experienced pump technician.

Bypass is usually achieved using femoral-femoral bypass. The cardiopulmonary bypass pump can provide complete hemodynamic and respiratory support during the resuscitation.^{87,95,96} Core body temperatures can be raised 1°C to 2°C every 3 to 5 minutes with flow rates of 2 to 3 L/min. Use heparin-bonded tubing if available to avoid systemic anticoagulation. This technique is extremely resource intensive, not readily available in many institutions, and requires specific expertise with respect to surgical and mechanical techniques.

EXTRACORPOREAL MEMBRANE OXYGENATION

There are multiple case reports of extracorporeal membrane oxygenation (ECMO) success in severe hypothermia (Chapter 73).^{8,97-99} Patients with core temperatures as low as 13.8°C, with 5 hours of CPR, and with 83 minutes of complete cold water submersion have been reported to have a good neurologic outcome after ECMO.^{97,100} Some are reporting successful use in trauma cases.⁹⁸ Hypoxemia, cardiac arrest, and asphyxia are recognized as major predictive adverse factors for survival and/or poor neurologic outcome in the hypothermic patient.^{99,101} ECMO provides appropriate support for cardiac and pulmonary functions with the added benefit of allowing for hemodialysis for restoration of electrolyte abnormalities and acid-base imbalances. ECMO administration in severe hypothermia has significantly improved survival and neurologic recovery when compared to lavage techniques. **Patients with severe hypothermia should be preferentially transported to hospitals where ECMO is available even if this prolongs transport times.**

The main obstacle to initiation of ECMO is the process of cannulation and setting up the apparatus (Chapter 73). Starting ECMO takes 134 minutes on average and requires specialized personnel.^{83,84} A new device and technique termed portable and percutaneous cardiopulmonary bypass (PPCPB) has been under investigation. PPCPB does not require heparinized tubing or advanced surgical technique. It can be initiated by an Emergency Physician. The process involves simple large vessel arterial and venous access. Set up requires 48 minutes on average. PPCPB has all the benefits of ECMO and warms patients by approximately 4°C/hr.^{83,84} PPCPB has improved outcomes in severe hypothermia with and without cardiac arrest when compared to other invasive techniques (e.g., lavage) and comparable outcomes to ECMO.⁸⁴ Refer to Chapter 73 for the complete details of ECMO.

ALTERNATIVE TECHNIQUES

There has been much research regarding the induction of therapeutic hypothermia. This has resulted in the development of a variety of external and internal cooling devices. They can easily be used to manage the hypothermic patient while not specifically designed to treat hypothermia.¹⁰² Reports have been published using endovascular cooling catheters to warm hypothermia patients with good outcomes.¹⁰³ These devices use a special central catheter that is placed the same way as central venous lines and warm patients by 0.5°C/hr to 2.5°C/hr.⁶⁸ New esophageal cooling devices can be used to warm patients but no data on warming accidental hypothermia patients have been published.¹⁰⁴⁻¹⁰⁶ These devices are placed in a similar manner to nasogastric tubes.

SUMMARY

The management and prevention of hypothermia in the Emergency Department is a challenging and perpetual task. The resuscitation of a severely hypothermic patient in full cardiorespiratory arrest can push the Emergency Physician and the Emergency Department

to the limit of their abilities and resources. The challenge in dealing with hypothermia lies in recognizing and managing the risk of hypothermia in the “routine” patient who presents every day. It is not possible to overstate the importance of continuity of care and the necessity of good communication as the patient is moved from the Emergency Department to either the Operating Room or the Intensive Care Unit so that rewarming efforts may continue.

Hyperthermic Patient Management

Jessica Mann and J. Elizabeth Neuman

INTRODUCTION

The evaluation and management of hyperthermia and heat stroke can be difficult and challenging in the Emergency Department (ED). **Heat stroke is defined as a core body temperature equal to or greater than 40°C with associated central nervous system dysfunction.¹ Heat stroke is a multisystem insult.** There are two types of heat stroke, the classic nonexertional heat stroke and the exertional heat stroke. Classic heat stroke affects individuals most often over 70 years of

age with underlying chronic medical conditions that impair thermoregulation, prevent removal from a hot environment, interfere with access to hydration, or interfere with attempts at cooling.² Exertional heat stroke generally occurs in young healthy individuals who engage in heavy exercise during periods of high ambient temperature and humidity. Typical patients are athletes and military recruits in basic training.³ More than 300 people die of heat-related illness in the United States each year.^{4,5} This can more than double in years with prolonged heat waves.⁶ Exertional heat illness is one of the leading causes of death in young athletes each year.^{5,7} Heat stroke is an uncommon medical emergency. It is considered one of the most important of all the environmental illnesses because of its potential for high morbidity and mortality in large numbers.⁸ Major complications of heat stroke include seizures, adult respiratory distress syndrome (ARDS), acute renal failure, liver disease, rhabdomyolysis, disseminated intravascular coagulation, and death.⁹

The patient must be exposed adequately. Cooling must be initiated in the quickest and most efficient manner possible as stabilization is occurring. Rapid cooling is the most effective strategy for minimizing morbidity and mortality from heat stroke and should be initiated as soon as possible and within 30 minutes of presentation.¹⁰ The most effective means of cooling remains controversial. Few controlled studies are available to determine the best method for achieving rapid cooling of patients. The techniques rely upon prompt recognition of symptoms, immediate intervention in the prehospital setting, a complete diagnostic evaluation in the ED, and the continued care in the ED. Begin cooling the patient in the prehospital setting by removing the patient from the heat stress, removing any excess clothing, keeping the skin wet, and fanning the patient in transport.

Continuous core temperature monitoring with a rectal or esophageal probe is mandatory. **Cooling measures should be stopped once a temperature of 38°C to 39°C has been achieved to reduce**

the risk of iatrogenic hypothermia.¹¹ Cooling must precede the investigation for the cause. Evaporation and convection are the simplest and most efficient means of cooling victims of heat stroke or heat exhaustion. Skin blood flow is preserved as compared with the use of ice because evaporation and convection are much more efficient modes of heat exchange.¹² Evaporation of 1 gm of water dissipates approximately seven times more heat than melting the same quantity of ice.⁴

The information in this chapter primarily pertains to hyperthermia from heat-related illness. Some of these techniques may be also used for other causes of hyperthermia. These include endocrine disorders, head injury, infection, intracranial hemorrhage, malignant hyperthermia, neuroleptic malignant syndrome, sepsis, serotonin syndrome, stroke, toxins, or other causes. Consider discussing the use of these techniques to treat hyperthermia with the appropriate consultant if the etiology is not heat-related.

ANATOMY AND PATHOPHYSIOLOGY

The classification of heat illness is controversial and there continues to be much disagreement about the general categories of illness. The International Classification of Diseases (ICD) published by the World Health Organization (WHO) offers a logical approach to categorizing the various forms of exertional heat illnesses.¹³ Diagnoses include heat edema, heat cramps, heat syncope, heat exhaustion, and heat stroke (**Figure 227-1**). Heat edema is self-limited. The patient presents with edema of the hands, feet, and ankles. This usually occurs in the first few days of heat acclimatization. Heat cramps occur most often in individuals who sweat profusely and are exercising or walking. Numerous factors contribute to the development of muscle cramps that include dehydration, loss of sodium, loss of potassium, extreme environmental conditions, and neurogenic fatigue.¹⁴ Heat syncope is dizziness or syncope after exposure

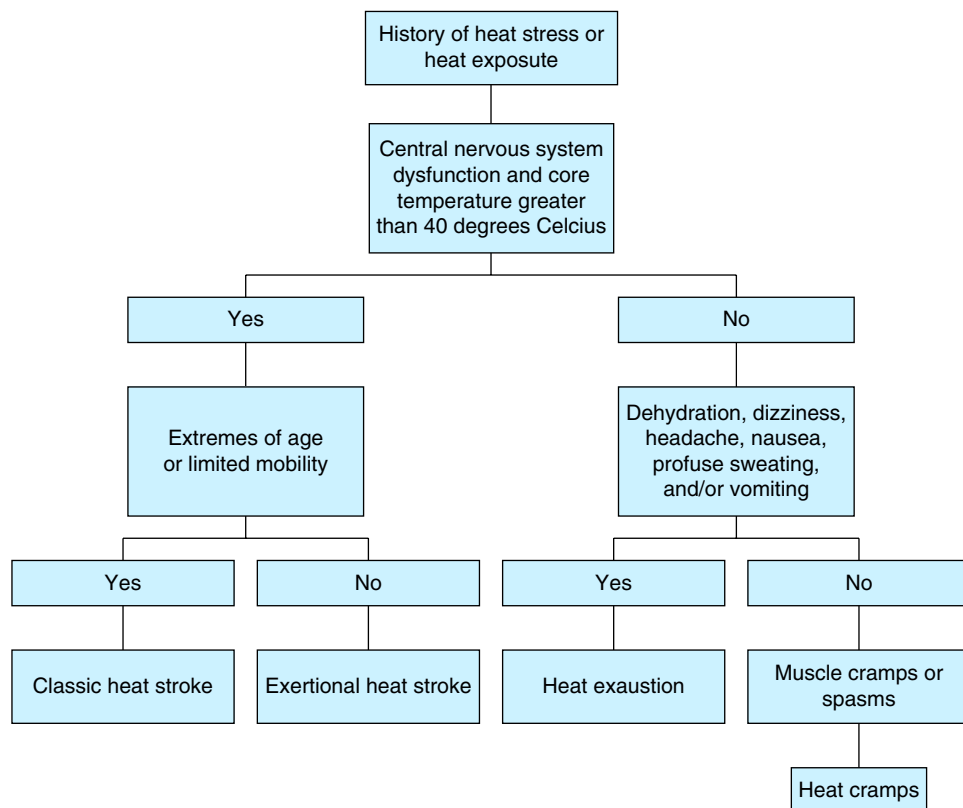

FIGURE 227-1. The types of heat-related illness.

to high temperatures. It is caused by vasodilatation with subsequent decrease in venous return and postural tone. Heat exhaustion is due to the inability to maintain adequate cardiac output. This can result from the excessive loss of body water, electrolytes, or both. The patient may complain of headache, nausea, vomiting, malaise, and myalgias. Heat exhaustion is distinguished from heat stroke in that there is no significant dysfunction of the central nervous system. Any mental status changes associated with heat exhaustion are mild and resolve quickly with rest.

Management of the heat stroke victim can be difficult. This is even after the successful initial resuscitation and stabilization. **Heat stroke is a multisystem insult that affects virtually every organ system.**^{11,15-23} Neurologic complications of hyperthermia include seizures, cerebral edema, delirium, and localized brain hemorrhages. Irreversible brain damage often occurs above 42°C or 108°F. Cerebellar impairment may persist after recovery. Cardiac complications include tachydysrhythmias, high-output heart failure, and myocardial injury. Cardiac dysfunction and tachydysrhythmias usually resolve with cooling. Pulmonary edema may be cardiogenic in patients with a limited cardiac reserve or secondary to ARDS. Pulmonary aspiration can be encountered in obtunded patients. Patients may also have bronchospasm, pulmonary infarction, and pulmonary hemorrhage. Acute renal failure may be due to direct heat damage, renal hypoperfusion, or rhabdomyolysis. Mucosal ulceration of the gastrointestinal tract is common and can lead to hemorrhage. Hepatic damage and dysfunction are common. The extent of hepatic necrosis and cholestasis may not be apparent until 48 to 72 hours after the heat injury. Hepatic injury is usually self-limited but may progress to fulminant failure and require a liver transplant. Hematologic complications include hemolysis, thrombocytopenia, and disseminated intravascular coagulation. Disseminated intravascular coagulation, triggered by diffuse endothelial and organ damage, is usually delayed 2 to 3 days in onset and is associated with a high mortality. Replacement of clotting factors with fresh frozen plasma and platelets may be necessary.

Heat stroke must be suspected in any patient who has acute mental status changes or other signs of central nervous system dysfunction in the setting of a high core temperature and a history of heat exposure. The initial temperature is usually at least 40°C to 42°C or 104°F to 108°F. Central nervous system dysfunction may manifest as varying degrees of confusion, obtundation, seizures, delirium, or focal neurologic deficits.

Core body temperature is maintained within close limits by a balance between heat production and heat dissipation. Muscular and metabolic activity along with absorption of heat from the environment results in a heat load on the body. Most fevers encountered

are a response to microbial invasion. Some fevers are due to exposure to high temperatures or abnormalities in the thermoregulatory apparatus.²⁴ The body temperature is controlled by the preoptic nucleus of the anterior hypothalamus. Factors that may compromise protective thermoregulatory mechanisms include chronic illness, psychiatric disorders, cardiovascular disease, endocrine disorders, nutritional deficiencies, metabolic disorders, infection disorders, medications, substance abuse, poor judgment, or extremes of age (**Table 227-1**).^{9,25,26}

It has been speculated that oxidative phosphorylation becomes uncoupled and enzyme systems cease to function when temperature regulation is lost and the core body temperature exceeds 42°C or 108°F. Energy stores become depleted as maximum metabolic demands escalate. This causes the cell membranes to become increasingly permeable thus increasing sodium influxes. These phenomena have been postulated to be part of a positive feedback loop involving progressive depletion of adenosine triphosphate (ATP), increased ion flux, increased rates of membrane depolarization and neurotransmitter activity, and a subsequent increase in heat production. Cell membranes eventually lose their integrity. Heat production accelerates, proteins denature, and widespread necrosis occurs as temperature-control mechanisms fail and leads to organ failure. Cellular damage occurs due to the elevated temperatures and the length of exposure to heat.^{9,27-29} **Tissues at greatest risk for heat-related damage include the vascular endothelium, neural tissue, hepatocytes, and kidneys.**

There are numerous mechanisms of heat dissipation including evaporation, radiation, convection, and conduction. Evaporation is the principal mechanism. It is the conversion of a liquid to the gaseous phase. Evaporation becomes the dominant mechanism of heat loss as ambient temperatures rise.^{27,30} Radiation is the transfer of heat to objects not in direct contact with the subject. Radiation accounts for approximately 65% of heat loss in cool environments. It is a major source of heat gain in hot climates. Convection is the transfer of heat to circulating fluid or gas. The amount of heat dissipated by convection becomes minimal as ambient temperature rises. Convective heat loss varies directly with wind velocity. Conduction is the direct transfer of heat to another object by direct contact.

INDICATIONS

Cooling will not harm patients who are hyperthermic regardless of the etiology. Cooling can be lifesaving in those with true heat stroke. Heat stroke may be difficult to identify if cooling was initiated in the field and the patient's mental functioning is intact. **Initiate cooling immediately if there is any doubt.**⁹

TABLE 227-1 Factors Related to Hyperthermia

Illness	Medications	Behaviors	Groups	Toxins
Autonomic neuropathies	Anticholinergics	Confining garments	Athletes	Alcohol
Cardiovascular disease	Antihistamines	Hot environments	Elderly	Amphetamines
CNS tumors	Antipsychotics	Inability to care for self	Infants	Cocaine
Dehydration	Diuretics	Injudicious exertion	Military recruits	Hallucinogens
Delirium tremors	Lithium	Poor fluid intake	Neonates	
Diabetes	MAO inhibitors	Social isolation	Prior heat stroke	
Hyperthyroidism	Neuroleptics		Psychiatric	
Major burn scarring	Phenothiazines			
Parkinson's disease	Salicylates			
Pheochromocytoma	Serotoninerigics			
Psychosis	Sympathomimetics			
Thyroid storm	Thyroid replacements			
	Tricyclic antidepressants			

CNS, central nervous system; MAO, monoamine oxidase.

CONTRAINDICATIONS

Evaluation and resuscitation of every patient always begins with assessment of the patient's airway, breathing, and circulation despite the need for immediate cooling. **Any life-threatening or limb-threatening conditions must be addressed simultaneously or before proceeding to cooling measures.**

Typical fever treatments are not indicated in the treatment of hyperthermia. The use of antipyretics such as acetaminophen and nonsteroidal anti-inflammatory drugs is not effective in treating hyperthermia due to heat-related illness. Do not administer medications used to treat malignant hyperthermia, neuroleptic malignant syndrome, or serotonin syndrome.³¹ These treatments do not work for heat-related hyperthermia.

There are specific contraindications to the individual cooling techniques. Ice water immersion is harmful to elder patients. It is difficult in patients with certain intravenous (IV) access (e.g., intraosseous) or monitor connections. Ice water immersion is also contraindicated in patients with seizures or airway compromise. Iced gastric lavage is contraindicated in patients with altered mental status or depressed airway reflexes unless they are endotracheally intubated or if nasogastric intubation (Chapter 77) is contraindicated. Iced peritoneal lavage should not be performed if the placement of a peritoneal lavage catheter (Chapter 84) is contraindicated.

EQUIPMENT

- Core thermometer (esophageal, rectal, or urinary)
- Large fans
- Spray bottles with a misting nozzle
- Water
- Ice
- Immersion tub
- Ice packs
- Wet sheets and towels
- Cooling blanket
- Peritoneal lavage kits
- Nasogastric tubes
- Iced saline

PATIENT PREPARATION

Immediately remove the patient from the heat-stress environment. Explain the cooling techniques to be employed to the patient and/or their representative. Remove the patient's clothes. Stabilize the patient's airway, breathing, and circulation as necessary. **Patient outcome is directly related to the length of time the tissues are exposed to the thermal challenge.** Apply cardiac rhythm monitoring, a noninvasive blood pressure cuff, and pulse oximetry. Place an esophageal (if the patient is intubated), rectal, or urinary temperature probe to monitor the patient's core body temperature. **Do not use any other routes for obtaining temperature as they are not accurate.**³²

TECHNIQUES

EVAPORATION

This technique is simple, does not interfere with patient care, and is noninvasive. It causes very little to no discomfort to the conscious patient. An additional benefit to evaporation is the access to the patient should other interventions be necessary.³⁰ This method is the most common for treatment of classic heat stroke. Completely wet the exposed patient with tepid water. Place large and powerful fans to strategically direct high-flow air currents toward the patient's head, feet, and torso (**Figure 227-2**). Spray the patient with a mist of tepid water from the spray bottles. Keeping the patient "wet and windy" provides a state-of-the-art cooling method for even the smallest ED without the need to purchase new or specialized equipment. Place ice packs wrapped in wet towels on the patient's groin, axilla, and neck.

Discontinue evaporative cooling when the core body temperature reaches 39°C or 102°F. Continued cooling can result in hypothermia as the core temperature continues to decrease after evaporative cooling is discontinued. Monitor the patient to ensure that their core body temperature does not increase.

The concept of evaporative cooling gained popularity with the Makkah Body Cooling Unit (BCU) (**Figure 227-3**). The Makkah BCU is used to provide field treatment for people participating in the annual pilgrimage to Mecca who may develop heat stroke. The Makkah BCU has been found to provide the fastest core temperature cooling rates of 0.31°C/min.²⁷ Today there are multiple options

FIGURE 227-2. Large fans at the head, foot, and side of the bed to direct high-flow air currents.

FIGURE 227-3. The first body cooling unit. (Photo courtesy of Science & Society Picture Library.)

of special beds called body cooling units available. They are expensive, require special training, take a significant amount of room for storage, and are usually not available in the ED.

ICE WATER IMMERSION

Immersion in an ice water bath is the most common and best method of cooling exertional heat stroke patients.³³⁻³⁵ Immerse the patient in a tub of ice water for 10 to 40 minutes (**Figure 227-4**). Water temperature should be between 2°C and 15°C (35°F and 60°F). Cover the patient's body as much as possible. Circulate the ice water vigorously while cooling. Briskly massage the patient's extremities to maintain peripheral circulation and promote heat loss. Monitor the patient's core temperature carefully. Rectal temperatures will decrease approximately 0.16 to 0.21°C/min.^{9,27}

Ice water immersion has limited use in the ED.^{27,30} Preparing an ice bath can result in a delay in cooling the patient. Contact with the ice water results in intense vasoconstriction which blocks heat exchange, paradoxically increases core body temperature, induces shivering, and is uncomfortable for the patient. Heat transfer from the core to the surface is reduced. The practical issues of impairing access to the patient, monitoring the airway, and initiating resuscitative measures are challenging when the patient is in an ice water bath.^{27,30,36} The tub and patient lift device are large, bulky, and not often available in the ED. Multiple caregivers are required to prevent the patient from drowning and to maintain their head above water.

FIGURE 227-4. Ice water immersion to cool a hyperthermic patient.

A simpler and easier method is immersion of just the patient's hands and forearms.³⁷ This method requires less patient cooperation than full-body immersion. It also allows for full patient monitoring during the cooling process. Another alternative is iced water therapy. The patient is placed supine on a porous stretcher that is positioned on top of a tub of ice water. Ice water is continuously poured onto the patient, ice packs are placed onto the patient (in the axillae, neck, and groin), and major muscles are massaged to increase skin vasodilation.³⁸

ICE PACKING

Packing the heat stroke patient in ice is an alternative to ice water immersion. It can result in conductive heat loss that is as effective as evaporative cooling. Patients who are awake and alert do not often tolerate ice packing. Its use may require parenteral sedation. The complications and practical limitations are similar to those of ice water immersion.

Place the undressed patient in the center of the gurney. Completely cover the patient with ice. This technique requires a large quantity of ice which may be unavailable in the ED. Consider placing plastic sheets or trash bags, with the edges curved upward, under the patient to prevent the ice and water from spilling onto the floor. Health-care personnel may otherwise slip on the wet floor, fall, and sustain injuries. Ice should be replenished as soon as there is notable melting present. An easier alternative is to place the patient in a body bag and fill this with ice. Discontinue cooling when the core temperature reaches 39°C or 102°F.

ICE PACKS

The placement of ice packs over select body areas is a more reasonable option than ice water immersion or ice packing. It may be used as the sole cooling method or in conjunction with evaporative cooling. Place plastic bags filled with ice or ice water in the patient's neck, axilla, and groin areas. These regions are near large blood vessels. The ice should be exchanged once notable melting is present. Remove the ice packs when the core temperature reaches 39°C or 102°F.

An alternative to ice packs is the EMCOOLS pads (EMCOOLS, Vienna, Austria).³⁹⁻⁴² These products are surface cooling pads that are nontoxic and designed for easy cooling, mobile cooling, and efficient cooling without the mess of ice water or the need for ice (**Figure 227-5**). The HypoCarbon technology provides better thermal conductivity when compared to water or ice. They are disposable, single-use, and frozen in a regular freezer ahead of being needed. The pads come with a peel-and-stick adhesive on the back for easy contouring to the patient's body. The pads can be used pre-hospital and in the ED. They are radiologically transparent allowing the cooling to continue while the patient is in the computed tomography scanner, magnetic resonance imaging scanner, or Radiology Department.

ICED PERITONEAL LAVAGE

Peritoneal lavage in hyperthermia has been investigated in canine models but used infrequently in humans. The advantages of this technique include the large surface area exposed to iced saline and direct cooling of the core. This technique is invasive and time consuming, requires significant equipment and expertise, and is associated with significant complications. A case report of a comatose patient with rectal temperature exceeding 42.5°C indicated that iced peritoneal lavage with 2 L of normal saline was successful in decreasing the rectal temperature to 39.4°C.¹² The patient had responded only partially to external evaporative cooling and iced gastric lavage.

D

FIGURE 227-5. The EMCOOLS pads. **A.** The self-adhesive pads. **B.** The pads on a person. **C.** Contoured pads for the neck and shoulders. **D.** The use of contoured pads. (Photos courtesy of EMCOOLS.)

Place 1 L bags of normal saline or Ringer's lactate solution into an ice water bath to cool down. The technique is similar to that used for warming the hypothermic patient (Chapter 226). Iced peritoneal lavage should be reserved for the patient who is not responding to other methods of cooling.

ICED GASTRIC LAVAGE

Central cooling techniques have not been studied extensively. An alternative core cooling technique may be iced gastric lavage.^{24,43} This method has been compared to room-air cooling in an anesthetized canine heat stroke model.²⁴ Gastric lavage with iced tap water cooled the canine models rapidly and safely. The technique yielded cooling rates five to six times faster than in controls. Significant differences

in hemodynamic parameters were noted to return to baseline more quickly in the iced gastric lavage group than in the control group. The technique is similar to that used for warming the hypothermic patient (Chapter 226). Instill 10 mL/kg of iced sterile saline, allow it to dwell for 30 to 60 seconds, and suction out the fluid. Repeat the procedure as necessary. Potential hazards using this technique include aspiration, gastric mucosal injury, electrolyte imbalances with water lavage, water intoxication, and dysrhythmias.²⁴

ALTERNATIVE TECHNIQUES

There is active research regarding the induction of therapeutic hypothermia by intravenous cooling to produce a rapid reduction in core temperature. This research has primarily focused on those

with brain injury, post-cardiac arrest, and stroke. This has resulted in the development of a variety of externally applied and internally applied cooling devices (Chapter 225). While not specifically designed to treat hyperthermia, they can easily be used to manage the hyperthermic patient. Some of these devices may be favorable in the prehospital environment or when other supplies are not readily available. The Emergency Physician may be using esophageal cooling in intubated patients in the future.⁴⁴ The first esophageal cooling device has been cleared in Canada and Europe (Advance Cooling Therapies, Chicago, IL). This technology is pending U.S. Food and Drug Administration approval at the time of this writing.

ASSESSMENT

Monitor the patient's core body temperature closely with an esophageal, rectal, or urinary temperature probe. Monitor the patient's vital signs, cardiac function, neurologic function, urine output, and laboratory measurements (e.g., arterial blood gases and serum electrolytes). Examination of muscle compartments and all orifices for bleeding is essential. Consider monitoring central venous pressure for assessing volume status to guide fluid resuscitation, especially in patients with heat stroke and limited cardiac reserve. Volume deficits may not be more than 2 to 3 L in patients with classic heat stroke. Hypotension usually responds to intravenous fluids. Use an inotrope, if required, that produces little vasoconstriction such as dobutamine. The use of H₂ blockers may decrease the incidence of gastrointestinal bleeding.²⁸ Treat rhabdomyolysis aggressively with saline diuresis, alkalization of the urine, and an infusion of 0.5 gm/kg of mannitol with or without furosemide.²⁸ Treat seizures with benzodiazepines.²⁸

AFTERCARE

Patients with minor heat-related illnesses may be safely discharged home after cooling. Instruct the patient to rest, drink plenty of fluids, and avoid the heat. Discuss with the patient the methods to remain cool if they are exposed to heat. This requires adequate rest, hydration before physical exertion, periods of rest during exertion when the individual can cool off, and adequate oral fluid intake during exertion. Arrange follow-up within 24 hours for a reevaluation.

Admission is prudent in several circumstances. Consider admitting patients with heat exhaustion for 23-hour observation if they have abnormal vital signs or abnormal laboratory investigations or if they remain symptomatic after fluid therapy. Patients with heat stroke should be admitted to an intensive care unit. Permanently altered and unstable thermoregulatory mechanisms have been observed in survivors of heat stroke which increases their susceptibility to future heat illness. **Prevention through education should be a part of every discharge plan.**

COMPLICATIONS

Complications can occur during the cooling of the hyperthermic patient. **Discontinue all cooling techniques when the core body temperature reaches 39°C or 102°F. Continued cooling can result in hypothermia as the core temperature continues to decrease after cooling is discontinued.**^{11,45} Monitor the patient to ensure that their core body temperature does not increase. The patient may experience muscle fasciculations, shivering, and agitation during the cooling process. These symptoms can be managed with intravenous benzodiazepines. Ice water immersion and ice packing make patient monitoring and management difficult if not impossible. Iced peritoneal lavage (Chapter 84) and iced gastric lavage (Chapter 77) are invasive procedures associated with significant potential complications.

SUMMARY

The best intervention for heat-related illness is prevention. Heat illness caught early responds to rest, exposure to shade and a breeze, and the ingestion of cool liquids. External evaporative cooling is acknowledged to be the safest means of cooling the hyperthermic patient. The tragedy of heat stroke is that it so frequently strikes highly motivated young individuals under the discipline of work, military training, or sporting endeavors. Heat-illness precautions should be implemented even in temperate zones during the hot summer months.

Autotransfusion

Carlos J. Roldan and Amit Mehta

INTRODUCTION

Trauma is the leading cause of death in children and adults under 44 years of age.¹ Exsanguination plays a significant role in as many as half of these deaths, with hemorrhagic shock the most common cause for potentially preventable death.² Hemorrhagic shock is a primary indication for the transfusion of homologous blood products. Transfusions with homologous blood products carry the possibility of associated complications including transfusion reactions, transmission of infectious diseases, and sensitization to antigens.³ Massive transfusions are associated with the additional complications of acidosis, dilutional coagulopathy, and hypothermia. Transfusion of homologous blood products in the trauma patient has

been independently associated with an increase in both morbidity and mortality, particularly when transfusing older stored blood products.⁴⁻⁶ Blood centers have more than doubled the prices of blood products in recent years due to a decline in blood donors, higher skilled labor costs, and increases in the cost of testing and processing blood.⁷ There is evidence that the best replacement for whole blood loss may be fresh whole blood.⁸

Alternative transfusion strategies have been developed for elective surgeries. These include autologous (i.e., acute) normovolemic hemodilution, autologous preoperative donation, autologous priming on bypass initiation during extracorporeal membrane oxygenation (ECMO), and intraoperative cell salvage with autotransfusion.⁹ The first two are not possible in the Emergency Department (ED). Cell salvage with autotransfusion represents a viable alternative to autologous transfusion in the ED but has received limited attention in the trauma patient.

An autotransfusion was first performed in the trauma setting by Elmendorf during the First World War on a soldier with a traumatic hemothorax.¹⁰ It was subsequently used sporadically as a lifesaving procedure.¹¹ A modified autotransfusion for a traumatic hemothorax was described in 1978.¹² This technique was simple, safe, and easy to practice. It was used in approximately 400 patients with a traumatic hemothorax without any noticeable complications. This technique is still applicable to current practice with preliminary studies showing that transfusion of a patient's own blood is safe.^{8,13-15}

Many of the patients with a life-threatening hemothorax either die before reaching the ED or experience severe hemodilution that accounts for some deaths in the ED and the Operating Room. **Hypovolemic shock secondary to trauma is the most frequent indication for a massive blood transfusion in the ED. It is an indication for an autotransfusion.** Much of the controversy surrounding practice paradigms centers on the disagreement as to what constitutes the proverbial "perfect procedure."

An autotransfusion may occur in the ED, Operating Room, and Surgical Intensive Care Unit with increasing frequency. **The shed blood is collected, mixed with an anticoagulant, concentrated, washed or filtered, and then returned through an intravenous (IV) line to the patient. Harmful contaminants (e.g., fat, free hemoglobin, and potassium) are removed from the salvaged blood.** This blood is returned through a 40 micron blood filter to collect particulate matter and microthrombi. An autotransfusion in the ED is usually limited to an acute traumatic hemothorax associated with clinically significant hypovolemia. **Utilization of blood from the chest cavity is ideal for autotransfusion since the bacterial contamination of this shed blood is minimal compared to shed blood in other areas.**⁸

INDICATIONS

Consider an autotransfusion with the anticipated loss of at least 20% of the patient's estimated total body blood volume. Consider an autotransfusion if the ED cannot obtain or provide cross-matched compatible blood. It can be used for the patient unwilling to accept homologous blood but willing to accept salvaged blood. The average amount of blood to be autotransfused should be expected to be greater than 1 unit to make this procedure cost effective.¹⁶⁻¹⁸

There are numerous advantages to an autotransfusion.^{15,19} It is convenient and immediately available as a blood product replacement. The blood is already warmed and at, or just below, body temperature. It addresses any special needs of the patient (e.g., religious preferences or a rare blood type). There is no chance of allergic reactions, alloimmunization, disease transmission, febrile reactions, and transfusion reactions. An autotransfusion requires no work on the part of the blood bank, has no compatibility issues, and ensures that the patient receives compatible blood. It conserves homologous

blood products for other patients. An autotransfusion results in the blood having a normal pH, viable platelets, and viable clotting factors when compared to homologous blood supplies. Higher levels of 2,3-diphosphoglycerate in autologous blood results in the easier release of oxygen from hemoglobin in the tissues. There is the positive psychological benefit to the patient when they are informed that they received their own blood.

CONTRAINDICATIONS

There are numerous contraindications to the use of an autotransfusion. The presence of a coagulopathy regardless of its etiology or when it occurs (i.e., in the ED, preoperative, intraoperative, or postoperative) or evidence of disseminated intravascular coagulopathy (DIC) may be more optimally managed with the administration of specific blood component therapy. Evidence or suspicion of serious infectious processes (e.g., mediastinal, pericardial, respiratory, or systemic) precludes the use of an autotransfusion. Do not autotransfuse blood if there is the presence of a malignant neoplasm at the collection site (i.e., abdominal or chest cavity) that can lead to possible contamination of the blood with malignant cells. Do not autotransfuse blood that is collected from a potentially contaminated abdominal or thoracic cavity (e.g., esophageal tear). Do not autotransfuse from a cavity that was irrigated with a solution that can cause lysis of red blood cells prior to blood collection and potentially precipitate end-organ damage if the salvaged product is administered. This includes alcohol, hydrogen peroxide, hypotonic irrigation solutions, povidone iodine antiseptic gels or solutions, or sterile water. Do not autotransfuse blood collected from body cavities that have had the administration of topical thrombin or microfibrillar hemostatic agents. Patients with renal or hepatic failure may not tolerate the increased levels of plasma-free hemoglobin or potassium that occur with an autotransfusion. Relative contraindications include cesarean delivery and sickle cell disease.

EQUIPMENT

- Sterile gloves and gown
- Face mask with a face shield or goggles
- Cap
- Povidone iodine or chlorhexidine solution
- Chest tube drainage apparatus with either a water seal or a dry one-way valve
- In-line autotransfusion system blood collection bag
- Whole blood in-line microaggregate filter for reinfusion (usually 40 microns, but can vary between 20 and 170 microns)²⁰
- Nonvented blood compatible IV administration set
- 250 mL bag of sterile normal saline for priming of IV tubing and microaggregate filter prior to blood infusion
- Pressure bag for rapid blood infusion
- Blood warming system if it is anticipated that multiple units of blood will need to be infused to help prevent hypothermia²¹⁻²³
- Citrate anticoagulants
- Tube thoracostomy supplies (Chapter 40)

Anticoagulation for an autotransfusion in the ED setting is generally recommended to help prevent the formation of clots in the autotransfusion system. While the administration of anticoagulants can be beneficial, it is not without risk and its use and dosage are at the discretion of the treating Physician. Heparin anticoagulation is one option. The local administration of heparin can lead to the formation of platelet microaggregates and potentially lead to

systematic heparinization which can result in further hemorrhage in a patient who is already bleeding.²⁴

Citrate anticoagulants are considered local anticoagulants and are preferred over heparin. Citrate works by binding with calcium ions to inhibit the conversion of fibrinogen into the insoluble protein fibrin, preventing the blood from clotting. Citrate only binds with calcium. It only anticoagulates the blood it is collected with. The liver rapidly metabolizes the citrate once the anticoagulated blood is reinfused.²²

Citrate phosphate dextrose (CPD) is a commonly used anticoagulant. It is recommended to use 1 mL of CPD for every 7 mL of blood. It is difficult to estimate the amount of blood in a patient's chest cavity. One approach is to instill 60 mL of CPD into the autotransfusion bag, enough to anticoagulate 1 unit of blood. When 1 unit of blood has been collected (i.e., about 500 mL total volume of blood plus CPD), it may be reinfused or additional CPD may be added to continue the collection. Prepare a new collection bag if bloody drainage is ongoing and inject anticoagulant before disconnecting the filled collection bag for reinfusion. The CPD injection may be facilitated by using a volume-control IV chamber. Run the desired amount of CPD into the chamber and then infuse it via the IV tubing to the injection port.

Citrate phosphate dextrose adenine (CPDA) may be used as an anticoagulant at a ratio of 1 mL per 7 mL of blood. Some consider CPDA the anticoagulant of choice for an autotransfusion of a traumatic hemothorax. It provides a reduced pH mixture that is advantageous to the platelets. The CPDA solution maintains the viability of the platelets, reduces clot formation in autotransfusion equipment, plugs the blood filter with microemboli, and clots the IV lines.

PATIENT PREPARATION

Assess the patient for the signs and symptoms of hypovolemia, hypoperfusion, and/or a hemothorax. Describe the procedure, its risks, and benefits to the patient and/or their representative. Obtained written or oral consent, if possible.

This procedure requires strict aseptic technique. Clean any dirt and debris from the patient's chest wall. Don full sterile and personal protective equipment. This includes sterile gloves, a sterile gown, a face mask with an eye shield or goggles, and a cap. Apply povidone iodine or chlorhexidine solution to the skin over the chest wall and allow it to dry. Apply sterile drapes to delineate a sterile field.

Much preparation is required before starting an autotransfusion. The autotransfusion system requires prior assembly. Consider setting up the autotransfusion components for patients who are at high risk for a hemothorax before inserting the chest tube. Otherwise, blood that drains immediately upon chest tube insertion is lost to recovery. **Refer to all manufacturers' directions for use, warnings, and cautions regarding anticoagulant medications, microemboli filters, and IV blood administration sets prior to their use.** Prophylactic broad-spectrum antibiotics may be administered immediately before the chest incision is made for the tube thoracostomy or just prior to the reinfusion. Follow all hospital protocols for blood handling, waste disposal handling, and infection control. Insert a large-bore chest tube (Chapter 51).

TECHNIQUES

There are several manufacturers of chest drainage and autotransfusion systems. The Pleur-Evac System (Teleflex Medical, Research Triangle Park, NC) is one of the commonly used systems in many EDs.²⁵ The Atrium Chest Drain Autotransfusion System (Atrium Medical Corp., Hudson, NH) is the second of the two more commonly used systems (**Figure 228-1**).²⁶

Three different techniques for blood collection are in-line, self-filling, and continuous. The in-line autotransfusion blood bag is a

FIGURE 228-1. The Oasis 3650 chest drain system with autotransfusion blood recovery. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

standard bag that attaches to the chest drain (**Figure 228-2**). The self-filling autotransfusion bag incorporates a low vacuum that is activated to improve the flow of fluid from the chest drain into the bag (**Figure 228-3**). The final option is the continuous autotransfusion. It is used to directly reinfuse shed autologous blood via a blood compatible infusion pump, a microemboli blood filter, and a non-vented blood compatible IV administration set. This is a true closed system and reduces the potential for contamination. It does not require the clamping and unclamping of tubes, exchanging autotransfusion bags, and the interruption of chest drainage to change autotransfusion bags. It results in less exposure to the patient's blood with a closed system. It saves time and money by not changing autotransfusion bags, filters, and IV tubing. Unfortunately, this closed system is rarely available in the ED and requires additional training for its use.

The technique chosen depends upon the chest tube drainage system used in your institution. Some chest tube drainage systems allow for more than one technique to collect blood for an autotransfusion. The specific port locations and connections will vary slightly among the different manufacturers but the general concepts are relatively universal. The general technique will be described below. The specific steps depend upon the actual equipment available.

Attach the autotransfusion bag to the chest drain. Inject anticoagulant into the collection unit as soon as possible during or before the blood collection if this is required. Collect the blood. Blood may be reinfused when 1 unit of blood has been collected (i.e., about 500 mL of blood plus the volume of anticoagulant). Remove the filled autotransfusion bag and replace it with a new one containing anticoagulant. Discontinue blood collection when it is determined that an autotransfusion is no longer required or there is no further bloody drainage from the chest tube.

FIGURE 228-2. An in-line autotransfusion bag. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

Reinfuse the blood. Prime the IV blood administration and microemboli blood filter with sterile saline. Invert the autotransfusion bag so that the spike port points upward. Remove the protective cap covering the spike. Insert blood tubing into the spike port by using a constant twisting motion. Attach a microfilter onto the blood tubing. **Remove the air from the autotransfusion bag.** Keep the unit inverted and squeeze all the air from the bag carefully through the filter and the drip-chamber assembly to prevent an air embolus. Close the infusion set clamp. Invert the autotransfusion bag and suspend it from an IV pole with the plastic strap. Open the infusion set and flush the administration line to remove the air. Attach the distal end of the infusion set to the IV line. Infuse the blood using gravity or pressure.

Keep in mind some general principles when performing an autotransfusion. Do not hang or hand carry the autotransfusion bag by its tubing. Use the hanger provided. Replace the spike port cap immediately following removal of the blood filters and IV tubing to prevent air entering the system. The air vent must remain closed when not in use. A new microemboli blood filter

FIGURE 228-3. A self-filling autotransfusion bag. (Photo courtesy of Atrium Medical Corp., Hudson, NH.)

and IV blood tubing must be used for each autotransfusion bag. When using vacuum suction with the collection apparatus it is important to use the lowest level possible to reduce the risk of red blood cell hemolysis during collection.²⁷ The recommended starting vacuum pressure is 20 mmHg.^{21,28}

ASSESSMENT

Assess the patient's cardiopulmonary status and vital signs frequently during the autotransfusion and at least 1 hour after the autotransfusion is complete. Periodically monitor laboratory data to include arterial blood gas values, hematocrit, partial thromboplastin time, platelet count, prothrombin time, rapid thromboelastography

(r-TEG), and serum lactate.²⁹ Monitor and mark the amount and type of drainage from the collection system hourly for the first 8 hours and then every 2 hours as volume loss can cause hypovolemic shock. Evaluate and maintain drainage tube patency every 2 to 4 hours. Mark the drainage level on the outside of the drainage-collection chamber in hourly or shift increments. Document the assessments and laboratory values in the medical record.

AFTERCARE

Monitor the patient's clinical status in response to the infusion during the stay in the ED once the infusion of the autologous blood has started. This will involve monitoring their vital signs and other hemodynamic parameters, including central venous pressure.¹⁷ Monitor laboratory data to assess the success and possible complications of the autotransfusion process. This generally includes electrolytes, renal function, hemoglobin and hematocrit, platelet count, coagulation profile, DIC profile, and r-TEG to assess for a consumptive coagulopathy.¹⁷

The Emergency Physician, in conjunction with the nursing staff, must maintain the integrity of the autotransfusion system during the infusion of autologous blood. It is necessary to ensure the autotransfusion bag is replaced each time it is filled to prevent overflow of blood into the chest drainage apparatus. Ensure each collection bag has anticoagulant added to it prior to the collection of blood. A new microaggregate filter must be used for each collection bag prior to it being infused. Inspect the blood through the collection bag for evidence of clotting prior to infusing it. Discard the autotransfusion bag and do not reinfuse it if it contains clotted blood or particulate matter. Purge all the air from the collection bag, intravenous tubing, and microaggregate filter to prevent an air embolism. Observe the autotransfusion to ensure that the entire contents of the collection bag are not allowed to infuse through the microaggregate filter and intravenous tubing. The transfusion of shed blood collected under posttraumatic conditions should begin within 6 hours of initiating the collection at the longest to reduce the risk of bacterial overgrowth and minimize damage to the blood components during storage.³⁰

COMPLICATIONS

The complications from an autotransfusion are clinically insignificant if the proper technique is followed and if less than 3000 mL of blood is reinfused. Overall, the complications are categorized as hematologic and nonhematologic. Refer to Chapter 51 regarding the complications associated with a tube thoracostomy.

HEMATOLOGIC

A coagulopathy may occur in trauma patients following an autotransfusion. The autotransfusion has not been overwhelmingly proven to be the etiology.³ These patients are more likely to have other independent risk factors for a coagulopathy (e.g., acidosis and hypothermia).³¹ This makes it difficult to determine the contribution of the autotransfusion to the development of a coagulopathy.³¹ DIC is a rare complication that should be anticipated and treated accordingly. A dilutional coagulopathy may occur when greater than 3500 mL of autologous blood is transfused. Treatment includes administration of fresh frozen plasma and platelets to compensate for the proportional decrease in platelets and fibrinogen.³² Hemolysis of red blood cells can be secondary to mechanical factors during the collection process, the use of hypotonic irrigation fluids, excessive suction pressure, aspiration of clotted blood, or the use of hemolytic solutions (e.g., povidone iodine, hydrogen peroxide, or alcohol) to collect blood.^{33,34} Hemolysis can also occur secondary to the prolonged exposure of red blood cells to the serosal linings of

traumatized body cavities.³⁵ Thrombus formation may occur from increased plasma-free hemoglobin that promotes a procoagulant effect and increases the risk of free hemoglobin precipitation in the renal tubules.^{36,37}

NONHEMATOLOGIC

Particulate embolism has been reported to occur during and after an autotransfusion. Most components of the equipment are designed for single use. Re-sterilization or re-use may compromise the structural integrity and lead to device failure. An air embolism may result from inadequate use of the IV set or the microemboli blood filter. An air embolism has also been associated with the reinfusion of the entire autotransfusion blood bag contents that contain residual air and a pressurized infusion of the autotransfusion bag with the air vents open. Citrate toxicity and myocardial depression may occur after the rapid infusion of citrate anticoagulated blood. The clinical manifestations of citrate toxicity include a perioral tingling sensation followed by abdominal cramping and cardiac dysrhythmias. Citrate toxicity can be prevented by ensuring that the ratio is not greater than 1:5 of the citrate anticoagulant to blood. Sepsis in patients with an isolated hemothorax is considered only a minimal risk. Sepsis has been associated with the difficulty that exists in maintaining a completely sterile environment in patients receiving an autotransfusion.³⁸⁻⁴⁰

SUMMARY

An autotransfusion is a basic technique that is possible in the ED. It is not the standard of care under all settings. The procedure requires familiarity with the equipment, continuing education, and quality control. The successful incorporation of this procedure likely requires the establishment of guidelines and protocols by a multidisciplinary group including representation from Emergency Medicine and Trauma Surgery. This may be the reason it is underutilized in many EDs. Anticipation of which patients would benefit from this technique might be problematic and time consuming, especially when assembling equipment that may not be used frequently. Proper use of the devices can be advantageous to avoid the multiple complications associated to hypovolemic shock in trauma patients. The low risk of complications related to this technique makes an autotransfusion a viable option to a homologous transfusion.

Helmet Removal

Ashley N. Sanello and Atila B. Uner

INTRODUCTION

The helmeted person who becomes injured presents unique challenges to athletic trainers, prehospital healthcare providers, and Emergency Department personnel in providing the initial stabilization and management. Greater numbers of people are wearing helmets due to the helmet laws and increasing public awareness for the prevention of head injuries associated with recreational and athletic activities. This practice will limit the most severe outcomes from head trauma. However, the helmeted patient is not immune from life-threatening head and neck injuries. **Secondary injury due to improper helmet removal can adversely affect patient outcome.**^{1,2}

Helmets vary in size, type, and accessories based on the user's activity (**Figure 229-1**). They consist of a hard plastic, polycarbonate, and/or fiberglass shell over either a layer of foam covered by material, inflatable air bladders, or both. Bicyclists, kayakers, roller bladers, skateboarders, and skaters wear simple skull helmets. These helmets cover the top of the skull like a hat and have a strap that is snapped or clipped under the chin to maintain the helmet in position. Football, lacrosse, and hockey players use open-faced helmets. These may have clear visors and/or face cages whose bases are screwed into the helmets. Motorcyclists and racers often wear full-face helmets with or without retractable or removable visors.

Athletes playing football and hockey wear protective shoulder padding in addition to helmets. Because of the shoulder padding, their cervical spines are more adequately stabilized in comparison to those of helmeted motorcyclists without shoulder padding.^{3,4} Helmet removal with and without shoulder pad removal has been shown to result in head and cervical spine movement.^{5,6} This can increase the risk of spinal cord damage in the helmeted athlete with a cervical spine injury.^{3,4}

Current recommendations for sports-related helmet removal, such as in ice hockey and football, are to leave the helmet in place until the patient arrives to an Emergency Department or Trauma Unit.^{3-5,7-13} **The exception permitting the removal of an athlete's helmet in the field is when the helmet significantly delays lifesaving measures or if airway access is obstructed.**^{3,4,7,14} This may occur in the unconscious and/or apneic patient. Prehospital healthcare providers should be able to maintain an adequate airway, stabilize a patient's cervical spine, and control associated hemorrhage with removal of only the face plate, face guard, and chin strap of the helmet.^{7,8,12,13}

ANATOMY AND PATHOPHYSIOLOGY

The type and fit of protective equipment, the mechanism of injury, the patient's age, and physical development all influence cervical spine injury. There is a greater risk of injury when the helmet

is too loose. It has been noted that most people wear helmets that are too large for their heads. Inertia is defined as a body's ability to resist change of position and motion. A 4 pound helmet can exert 200 pounds of force on the wearer's head and neck when an impact occurs at 50 mph. Injury is often more serious when inertial forces cause excessive extension and flexion of the cervical spine without adequate protection for the lower head and neck.^{8,15}

The anatomic location of cervical spine injuries tends to differ between children and adults. The immature pediatric spine is more susceptible to flexion and extension injuries in the upper cervical (i.e., C2 to C3) segments due to the child's proportionally larger head size, shorter neck with immature development, weak neck muscles, and the neck's higher degree of flexion and extension.^{8,15,16} The relative amount of cartilaginous tissue in comparison to bone makes the pediatric patient more prone to spinal cord injury when subjected to high inertial forces. These injuries may be more difficult to detect on plain radiographs, as cartilaginous injuries are radiolucent.^{15,16}

Similar conditions of disproportionate head-to-neck size are artificially created in the helmeted patient. The motorcycle helmet will often cause hyperflexion of the neck. Flexion and extension injuries without adequate lower neck protection result in an increased incidence of upper cervical spine (i.e., atlantoaxial, C1, and C2) injuries in comparison to lower cervical spine segments.^{16,17} There is a greater incidence of lower cervical spine (i.e., C5 and C6) injury among football and hockey players because the shoulder padding offers support to the lower head and upper neck. It decreases the amount of flexion and extension at the time of impact.¹⁷ Head and neck restraint systems, such as the HANS (Head and Neck Support) device (HANS Performance Products, New Braunfels, TX) were developed for professional motorsport racers to prevent flexion-distraction injuries during high-velocity impacts. Since these devices are now required for use by many professional racing drivers and commercial drivers, they have significantly decreased fatal craniovertebral junction injuries.¹⁸ The removal of these devices depends on the brand the patient is wearing, but all require the device to be unclipped from the helmet and cervical stabilization held while the device is removed.

Flexion and distraction while removing a helmet may cause spinal cord compression as demonstrated in unstable C1 to C2 injuries with helmet removal in cadaveric models.¹⁷ Similar unfavorable results were demonstrated with neck flexion and extension during helmet and shoulder pad removal.¹⁷ The properly fitting helmet is tight enough that a significant force must be applied to remove it in the field thus increasing the chance of cervical spine movement. **Apply proper in-line cervical immobilization before helmet removal or medical intervention while avoiding in-line traction. In-line traction increases the risk of subluxation or distraction at the site of injury.**

It is recommended that the helmet and padding in an athlete not be removed in the field. Overzealous manipulation of the patient or improper helmet and/or padding removal can complicate an underlying injury. The helmet can be secured to a long backboard if one is used. Since many prehospital agencies no longer use backboards, another way to secure the helmet is to place

FIGURE 229-1. Types of helmets. **A.** Simple skull helmet. **B.** Football helmet. **C.** Partial face covering helmet. **D.** Full face covering helmet without a face shield. **E.** Full face covering helmet with a face shield.

blankets or towels next to the head and tape them to the helmet. **If shoulder pads or helmets are removed in the field, the posterior aspect of the neck and shoulders must be adequately supported while in-line immobilization is maintained to avoid further spinal cord injury.** Cervical immobilization, with and without helmet removal, is best accomplished with at least two people to assure that the patient's head and neck remain stable.

INDICATIONS

Sports-related injuries can be assessed and stabilized in the field without removing the helmet or shoulder pads.^{5,9-13} Once the patient is in the Emergency Department, it is best to remove the helmet to obtain an exam and possible imaging. The patient can sometimes be initially managed and radiographed and the cervical spine radiographically "cleared" prior to removal of the helmet in the Emergency Department.¹ Plain radiographs may be inadequate to visualize the bony structures if the helmet and pads remain on the patient.^{19,20} If attempts to remove the helmet cause severe neck pain or focal neurologic symptoms, a computed tomography scan can be done while the helmet is on to evaluate the cervical spine as most helmets and pads are nonmetallic.^{5,21}

Helmet removal is warranted emergently in patients who are apneic, in patients without an adequately sustainable airway, if the helmet interferes with airway management, if cardiopulmonary resuscitation (CPR) is required, and in patients who have uncontrollable hemorrhage.^{14,22,23} If airway access is required, it is safer to only remove the face mask in the prehospital setting in a potential spine injury than to remove the entire helmet.^{12,13} Helmets that are loose fitting or that do not adequately stabilize the head and neck should be removed. Other indications to remove a helmet include if it prevents proper patient immobilization or if the face mask cannot be removed. **When a helmet is removed, any pads and neck support devices attached to the pads must be removed to maintain the cervical spine in a neutral position and prevent secondary injury.**²⁴

CONTRAINDICATIONS

Adhere to strict cervical spinal cord injury precautions throughout the prehospital period. Do not remove the helmet unless absolutely necessary.²⁵ It is not possible to completely exclude a spinal cord injury or vertebral fractures in the field.

Consider delaying the removal until radiographically cleared if the patient is unconscious, has an abnormal mental status, is under the influence of ethanol or drugs, is intoxicated or potentially intoxicated, or has distracting injuries; if there is evidence of a spinal cord injury; if a complete physical examination cannot be performed; or if the patient has neck pain. The only exception is if the patient's airway and breathing cannot be supported with the helmet in place.

EQUIPMENT

- Adjustable cervical collar
- Scissors or shears suitable to cut the face mask
- Cast saw with spare blades
- Screwdrivers, flat head and/or Phillips head
- Face mask removal tools
- Towels

PATIENT PREPARATION

A complete examination, including a neurologic examination, should be done prior to the removal of a helmet. Explain the removal procedure and its possible complications to the patient and/or their

representative. Explain all the potential risks involved in helmet removal including the possibility of worsening an underlying spinal cord injury. The risk of permanent central nervous system damage should be stated as well as the fact that the precautions to avoid such injury are not foolproof but will be observed as carefully as possible. Answer any questions or concerns of the patient or their representative. **If the patient is awake and alert, instruct them to tell you immediately if they experience numbness, pain, paresthesias, or tingling during the removal procedure.**

Remove any removable parts if they were not detached from the helmet prior to arrival in the Emergency Department. The face mask, face shield, and/or visor can often be removed with a flat head screwdriver, a Phillips head screwdriver, or an electric screwdriver (i.e., battery operated or rechargeable).²⁶⁻³⁰ If the screws cannot be removed because they spin in place or are rusted, cut the plastic clips holding the face mask onto the helmet. Some face masks can be removed easily if they are attached to the helmet with a quick release system.³¹⁻³³ A variety of tools are available to aid in face mask removal.³⁴ The hospital's maintenance department can provide an anvil pruner, bolt cutters, or PVC pipe cutter. Commercial devices have been designed to remove a face mask. These commercial devices are not often available in the Emergency Department.

Carefully look for any damage to the patient's helmet. External damage to the helmet may be the only initial indication of the severity of the impact. Inspect the integrity of the helmet shell for fit and structural breaks. The patient may be wearing eyeglasses or sunglasses under the helmet. Remove the glasses before helmet removal begins. Contact lenses may remain in place until the helmet is removed.

The helmet will cause flexion of the cervical spine when a patient is placed supine. This flexion is even more pronounced in a child due to their large occiput. Place rolled towels or sheets under the patient's shoulders to eliminate the excessive flexion of the cervical spine. Such flexion is minimal and requires no towels under the shoulders if the patient is wearing shoulder pads in addition to a helmet.

TECHNIQUES

MANUAL ONE-PERSON TECHNIQUE

Helmet removal can be performed by one or two people. **Reserve the one-person technique for extreme situations as the two-person technique is preferred (Figure 229-2).** With only one person present, it is necessary to pad voids behind the patient's neck and shoulders (Figure 229-2A). **The goal is to keep the head and neck in the neutral position as much as possible while removing the helmet.**

Stand above the patient's head looking down toward their feet. Lift up the face mask, if present, and undo the helmet chin strap. Place the heels of both hands on the sides of the helmet (Figure 229-2B). Insert the index, middle, ring, and little fingers into the space between the patient's head and the helmet. **Gently spread open the helmet with both hands to create clearance between the helmet padding and the patient's face and ears (Figure 229-2B).** Slowly and gently remove the helmet (Figure 229-2C). **Stop removing the helmet immediately if the patient experiences pain or neurologic symptoms and use the two-person or cast saw technique.** If the helmet is of the full-face type, the lower part of the helmet may get hung up on the nose. If that occurs, gently tilt the helmet posteriorly and continue to pull it off until the nose is cleared. Return the helmet to a neutral position after the nose is cleared. **Avoid cervical spine hyperextension during this stage of helmet removal.**

Stop removing the helmet when the bottom of the helmet is just above the patient's occiput. Move the fingers of both hands onto

FIGURE 229-2. The one-person helmet removal technique. **A.** Patient positioning. **B.** The base of the helmet is spread open. **C.** The helmet is removed to expose the occiput. **D.** In-line immobilization is applied with the fingers. **E.** The helmet is pushed off with the heels of the hands. **F.** The helmet is removed while in-line immobilization is maintained.

the patient's occiput while keeping the heels of both hands on the helmet (**Figure 229-2D**). The fingers will now maintain stabilization and immobilization of the head and neck. Push the helmet off the patient's head using the heels of both hands while maintaining immobilization of the patient's head and neck (**Figures 229-2E and 229-2F**). Remove the shoulder pads if present. Maintain the head manually in line until immobilization can be accomplished with a cervical collar, backboard, sandbags, and/or tape.^{6,22,35}

MANUAL TWO-PERSON TECHNIQUE

The two-person technique has the same goals as the one-person technique (**Figure 229-3**). The assistant provides in-line immobilization while the helmet is removed.^{6,22,35} Instruct an assistant to stand at the patient's side at the level of the patient's neck and shoulders. Lift up the face mask, if present, and undo the chin strap. Place one of the assistant's hands under the patient's occiput and upper neck.

Place the assistant's other hand under the patient's mandible so that the mental process (i.e., the patient's chin) rests in the assistant's first web space (**Figure 229-3B**). Place the tip of the assistant's thumb on the angle of the patient's mandible. Place the index and long finger of the assistant's hand on the contralateral angle of the patient's mandible. Instruct the assistant to hold this position and maintain in-line immobilization of the patient's head and neck.^{6,36}

The procedure to remove the helmet is similar to that described above for the one-person technique. Stand above the patient's head looking down toward their feet. Place the heels of both hands on the sides of the helmet (**Figure 229-3B**). Insert the index, middle, ring, and little fingers into the space between the patient's head and the helmet. **Gently spread open the helmet with both hands to create clearance between the helmet padding and the patient's face and ears** (**Figure 229-3B**). Slowly and gently remove the helmet (**Figure 229-3C**). **Stop removing the helmet immediately if the patient experiences pain or neurologic symptoms and**

FIGURE 229-3. The two-person helmet removal technique. **A.** Patient positioning. **B.** An assistant provides in-line immobilization. The base of the helmet is spread open. **C.** Remove the helmet to clear the nose. **D.** The helmet is removed while the assistant continues in-line immobilization. **E.** The Emergency Physician provides in-line immobilization in addition to the assistant. **F.** The assistant has removed their hands and the Emergency Physician maintains the in-line immobilization.

use the cast saw technique. If the helmet is of the full-face type, the lower part of the helmet may get hung up on the nose. If that occurs, gently tilt the helmet posteriorly and continue to pull it off until the nose is cleared. Return the helmet to a neutral position after the nose is cleared. **Avoid cervical spine hyperextension during this stage of helmet removal.** Completely remove the helmet (Figure 229-3D).

The Emergency Physician's hands should be applied to the patient's head and neck to maintain the in-line immobilization (Figure 229-3E). Instruct the assistant to remove their hands (Figure 229-3F). Remove the shoulder pads if present. Instruct the assistant to apply a cervical collar and secure the patient's head. The Emergency Physician can now release hold of the patient. Maintain the head manually in line until immobilization can be accomplished with a cervical collar, backboard, sandbags, and/or tape.^{6,22,35}

CAST SAW BIVALVE TECHNIQUE

A cast saw (Figure 229-4) can effectively be used to cut through the shells of most helmets (Figures 229-5 and 229-6). This technique allows for removal of the helmet without cervical spine movement.^{1,2} **Cut the helmet off any patient with a neurologic injury, abnormal cervical spine radiographs, if there is a concern for head and neck trauma, or if the helmet is extremely snug-fitting to prevent cervical spine movement.** This technique requires the presence of two providers.^{1,2}

Protect the patient from secondary injury from the cast saw, the helmet-cutting process, and the sharp edges of the helmet. Instruct the responsive patient to keep their eyes closed throughout the cutting and removal process to prevent corneal foreign bodies, corneal abrasions, and globe penetration. Place a moist towel over

FIGURE 229-4. The cast saw.

the patient's face for protection. Explain that there may be sounds of material or Velcro being torn or pulled with the helmet and not to be alarmed. Warn the patient about the noise associated with cutting the helmet with the cast saw. Protect the patient's eyes from exposure to foreign body penetration or abrasions if they are unresponsive. This includes taping the eyelids closed and placing a moist towel over their face.

Instruct the assistant, as described above for the two-person technique, to stabilize and immobilize the patient's head and neck (Figure 229-5B). Cut the helmet from ear to ear in a coronal plane with the cast saw (Figure 229-5C). **Carefully cut the padding and straps with a heavy scissors. Use care to not cut the patient's ears as well not force the tips of the scissors into their ears or scalp.** Remove the anterior portion of the helmet (Figure 229-5D). Gently slide out the posterior portion of the helmet while the assistant maintains in-line immobilization of the head and neck (Figure 229-5E). The Emergency Physician should then support the patient's head and maintain in-line immobilization (Figure 229-5F). Instruct the assistant to slowly and carefully remove their hands (Figure 229-5G). Remove the shoulder pads if present. Instruct the assistant to apply a cervical collar and secure the patient's head. The Emergency Physician can now release hold of the patient.

CAST SAW-FACE MASK REMOVAL TECHNIQUE

The cast saw-face mask removal technique can be used to remove the front part of a full-face helmet to secure the airway and then continue to remove the helmet without cervical spine movement (Figure 229-6).^{22,35,37} This procedure also requires two providers.^{21,22,35,37}

This technique allows for removal of the helmet without cervical spine movement.^{1,2} **Cut the helmet off any patient with a neurologic injury or abnormal cervical spine radiographs, if there is a concern for head and neck trauma, or if the helmet is extremely snug-fitting to prevent cervical spine movement.** This technique requires the presence of two providers.^{1,2} Push the plastic eye shield up and unclip the chin strap.

Protect the patient from secondary injury from the cast saw, the helmet-cutting process, and the sharp edges of the helmet. Instruct the responsive patient to keep their eyes closed throughout the cutting and removal process to prevent corneal foreign bodies, corneal abrasions, and globe penetration. Place a moist towel over the patient's face for protection. Explain that there may be sounds of material or Velcro being torn or pulled with the helmet and not to be alarmed. Warn the patient about the noise associated with cutting the helmet with the cast saw. Protect the patient's eyes from

exposure to foreign body penetration or abrasions if they are unresponsive. This includes taping the eyelids closed and placing a moist towel over their face (Figure 229-6B).

Instruct the assistant, as described above, to stabilize and immobilize the patient's head and neck. Hold the cast saw with the dominant hand while the nondominant hand is placed between the inner helmet and the patient's face (Figure 229-6C). This protects the patient's face and helps gauge the depth to cut. Cut the helmet starting at one side of the face mask (Figure 229-6C). Repeat this process and cut the second side of the face mask (Figure 229-6D). Remove the hard plastic front of the helmet, which includes the face mask, to expose the foam and fabric layer underneath. Use trauma shears to cut through the fabric and foam of the face mask to expose the patient's face (Figure 229-6E). After the airway is secure and/or spine imaging has taken place, if necessary, remove the rest of the helmet.

Gently spread open the cut ends of the helmet with both hands to create clearance between the helmet padding and the patient's face and ears (Figure 229-6F). Slowly and gently remove the helmet. **Stop removing the helmet immediately if the patient experiences pain or neurologic symptoms. Avoid cervical spine hyperextension during this stage of helmet removal.** Completely remove the helmet.

The Emergency Physician's hands should be applied to the patient's head and neck to maintain the in-line immobilization (Figure 229-5F). Instruct the assistant to remove their hands (Figure 229-5G). Remove the shoulder pads if present. Instruct the assistant to apply a cervical collar and secure the patient's head. The Emergency Physician can now release hold of the patient. Maintain the head manually in line until immobilization can be accomplished with a cervical collar, backboard, sandbags, and/or tape.^{6,22,35}

ALTERNATIVE TECHNIQUES

There are some devices that are easy to install, low cost, and often recommended or required for use by many professional racing associations and organizations. An example is the Eject Helmet Removal System (Stilo USA, Mooresville, NC). The safety of using this device compared to manual helmet removal seems to be comparative, but few studies have been done.³⁸ The device consists of an accordion-folded airbag, tubing that exits the airbag and clips onto the edge of the helmet for easy access, and an insufflation bulb (Figure 229-7).

It is available in two forms. The first is the individual unit that can be purchased and installed in the helmet by the person wearing the helmet. This is usually only done in professional racing. The second is the EMS Kit for prehospital and hospital personnel to use if the device is not preinstalled by the helmet wearer. The EMS Kit contains several of the devices, insufflation bulbs, an insertion tool, and CO₂ cartridges that can be used instead of the insufflation bulb.

The device is simple to use. One person is required to provide in-line immobilization to the cervical spine. A second person is required to activate the device and remove the helmet. If the device is preinstalled in the helmet, locate the tubing insufflation port. If it is not already preinstalled, then use the insertion device to place the airbag under the helmet. Attach the insufflator bulb (Figure 229-7A). Squeeze the insufflator bulb to inflate the airbag. Alternatively, attach the CO₂ cartridge to inflate the airbag. As the airbag inflates it will elevate and lift the helmet off the patient's head (Figures 229-7B and 229-7C). While one person maintains cervical spine immobilization, the other person should remove the helmet followed by removal of the pads if present. Apply a cervical collar and secure the patient's head.

FIGURE 229-5. The cast saw bivalve removal technique. **A.** Patient positioning. **B.** An assistant provides in-line immobilization. **C.** The helmet has been cut with a cast saw. **D.** The anterior portion of the helmet is removed. **E.** The posterior portion of the helmet is removed. **F.** The Emergency Physician provides in-line immobilization in addition to the assistant. **G.** The assistant has removed their hands and the Emergency Physician maintains the in-line immobilization.

FIGURE 229-7. The Eject Helmet Removal System. **A.** The system in place between the helmet and the patient's head. **B.** Inflation of the airbag releases the helmet and begins to elevate it off the head. **C.** The airbag is further inflated until the helmet is removed from the head.

ASSESSMENT

Reassess the patient after removing the helmet and securing their head and neck.³⁹ Examine the patient for secondary injury due to the helmet removal procedure such as abrasions, lacerations, and corneal foreign bodies. Perform and document a neurologic examination to ensure there is no change from the initial examination and that the helmet removal procedure did not result in an iatrogenic injury.

AFTERCARE

Clean and vacuum any helmet debris if the helmet was cut with the cast saw. This will prevent any of this material from getting into the patient's eyes or nose as well as preventing them from inhaling the debris.

COMPLICATIONS

The most concerning aspect of helmet removal is adequate immobilization of the patient's head and neck during the procedure. Gross movement of the head and neck can result in displacement of fractures, spinal cord injury, or exacerbation of a partial spinal cord injury. **Avoid any movement of the head and neck when there is any suspicion of a spinal cord injury or severe head trauma.** Some movement of the patient's head or neck is likely to occur during helmet removal. **Minimizing the amount of motion is paramount.**

Secondary injury to the ears, eyes, and nose can be avoided by using careful technique. Spreading open the sides of the helmet before removal in the one-person or two-person techniques will eliminate traction injuries to the scalp and ears.

A separate set of complications is applicable to the cast saw technique. Proper education of the patient is required to prevent them from moving because of the noise and vibration associated with this technique. Covering the patient's eyes and face with a moist towel will prevent corneal abrasions, corneal foreign bodies, oral and nasal foreign bodies, and inhalation of any debris. The cut edges of the helmet can be sharp. Careful removal will prevent cutting the patient's ears or scalp.

SUMMARY

The Emergency Physician who cares for trauma victims must be aware of the different types of helmets available and the means to safely remove them. Proper assessment of the helmeted patient will determine the need for emergent helmet removal. A thorough physical assessment and radiographic studies may take place prior to removing the helmet if the patient is stable upon the initial assessment. By using proper techniques, helmets may safely be removed without causing secondary injury.

Pneumatic Antishock Garment (MAST Trousers)

Evan J. Weiner

INTRODUCTION

The pneumatic antishock garment (PASG) is a device aimed at treating hypovolemic shock in the prehospital setting. Its primary purpose has been in the transport of patients with hemorrhagic shock due to trauma. It has been used in cases of nontraumatic hemorrhage (i.e., ruptured ectopic pregnancy and ruptured aortic aneurysm). The PASG is more commonly known as the Military Antishock Trouser, Medical Antishock Trouser, or MAST (**Figure 230-1**). The PASG was first invented during the Vietnam War.^{1,2} An earlier version called the “G-suit” dates to 1903 and served mainly to prevent postural hypotension and venous pooling in pilots.³

The evidence supporting PASG use is mixed. Initial reports described successes in increasing systemic blood pressure and controlling intra-abdominal hemorrhage in trauma patients with hypovolemic shock.^{4,5} A large retrospective analysis of 1120 PASG-applied patients in 1983 revealed a 24-hour survival rate of 73%.⁶ Approximately 84% of survivors had an increase in systolic blood pressure, a decrease in heart rate, or evidence of enhanced tissue perfusion. **Prospective studies have concluded that PASG provides no advantage to survival.**^{7,8} A Cochrane review concluded that there is no evidence to suggest that PASG reduces mortality or hospitalization.⁹ The Advanced Trauma Life Support (ATLS) course has previously supported its use “to control bleeding from pelvis or lower extremity fractures” but states that its use “should not interfere with rapid reestablishment of intravascular volume by intravenous fluid infusion.” It also cautions against prolonged application leading to compartment syndrome.¹⁰ PASG is not part of the current ATLS protocol.¹¹

Another garment called the Non-Pneumatic Antishock Garment (NASG) has been recommended by the World Health Organization (**Figure 230-2**). It acts as a temporizing measure for postpartum obstetrical hemorrhage in poorly resourced areas of the world.¹²

ANATOMY AND PATHOPHYSIOLOGY

The antishock garment works by several proposed mechanisms. The garment provides circumferential pressure on the abdomen and lower extremities. It can enhance venous return from the lower extremities

FIGURE 230-1. An example of a PASG.

A

B

FIGURE 230-2. An example of an NASG. **A.** The garment opened. (Photo courtesy of LifeWrap NASG.) **B.** The garment on a patient. (Used with permission from reference 22.)

and acts as an autotransfusion. The antishock garment produces a small autotransfusion effect. It can increase the total peripheral vascular resistance (PVR). The increased PVR provides the most blood pressure elevation. Its actions on the lower extremity vasculature lead to increased preload, afterload, stroke volume, and cardiac output.^{13,14} The antishock garment shunts the blood to the brain, heart, and vital organs. One study proposes that the antishock garment's blood pressure elevation effect may be due to sympathetic nervous system activation from the abdominal but not leg compression.¹⁵ The antishock garment can tamponade hemorrhage. The antishock garment can be useful for applying direct external pressure on pelvic or lower extremity bleeding. It puts indirect pressure on deep

structures. It may stabilize fractures (i.e., pelvic and femur) and tamponade bleeding.¹⁶ It has been shown to decrease blood flow to areas distal to the renal vessels.¹⁷ The antishock garment prevents bleeding into hematomas and the formation of hematomas.

INDICATIONS

There are no absolute indications for the use of PASG. Its main purpose is to function as an adjunct for uncompensated hypovolemic shock. PASG may be helpful in the situations of traumatic hypotension due to blunt abdominal trauma, major pelvic fractures, femur fractures, and lower extremity hemorrhage. It may be a reasonable adjunct in the prolonged prehospital transport of a hypotensive patient. The device assists in splinting pelvic and lower extremity fractures. Controversy exists regarding whether the PASG is useful in thoracic and penetrating abdominal trauma.

The antishock garment may be used for medical indications. It can be useful and effective for hypotension due to a ruptured aortic aneurysm.¹⁸ Other uses include anaphylaxis, gynecologic hemorrhage, postpartum hemorrhage, ruptured ectopic pregnancy, septic shock, and spinal shock.¹⁹⁻²²

CONTRAINDICATIONS

Absolute contraindications to use of PASG include congestive heart failure and pulmonary edema due to increased afterload. Suspected or actual lower thoracic spine and lumbar spine fractures can be made worse by the application and use of an antishock garment. A number of relative contraindications exist including cardiogenic shock, cardiac tamponade, myocardial infarction, penetrating thoracic trauma, diaphragmatic injury, lower extremity compartment syndrome, an impaled foreign body, abdominal evisceration, spinal instability, hemorrhage above the garment, and pregnancy (i.e., unless the PASG is not inflated or using a NASG).

EQUIPMENT

The most commonly available PASG is the MAST (**Figure 230-1**). The suit is made of three independently inflatable compartments (i.e., two leg compartments and one abdominal compartment) held together with Velcro. Newer versions are made of neoprene or urethane for prolonged storage between uses. The compartments are inflated with a foot pump and provide up to 104 mmHg in counterpressure regulated by individual pop-off valves. Each compartment has a stopcock to regulate the flow of air. The garment is available in three models and two sizes (i.e., adult and pediatric). One of the models is transparent and allows providers to monitor injury sites and gain access to insert femoral venous access (**Figure 230-3**). The antishock garment can be applied quickly and within 60 seconds.

The NASG is simple to apply (**Figure 230-2**). It is lightweight (1.5 kg), made of neoprene, and has Velcro closures. It is mostly used in low-income countries for postpartum hemorrhage.^{21,22} The abdominal panel stretches and a foam ball compresses the abdomen to reduce blood flow (**Figure 230-2**). The design allows access to the perineum for procedures (e.g., bladder catheterization and episiotomy repair). There are no compartments to inflate, stopcocks, and hoses.

PATIENT PREPARATION

Explain the risks, benefits, and alternative procedures to the patient and/or their representative. Include an explanation of the application process. An informed consent is not required. Examine the

FIGURE 230-3. An example of a transparent PASG. (Used with permission from www.hiveminer.com.)

patient thoroughly. Determine if the patient has any sharp objects in their clothing or on the lower extremities. Remove anything sharp to prevent the objects from penetrating the antishock garment or the patient. Reduce any extremity deformities. Examination of the

FIGURE 230-4. The three compartments of the PASG positioned on a gurney.

patient under the garment will be difficult once applied except when the transparent model is used.

TECHNIQUE

PASG APPLICATION AND INFLATION

Open each compartment of the PASG and place the compartments on a flat surface (**Figure 230-4**). Place the PASG on the patient. Place the patient supine on the open PASG, log-roll the patient and put the PASG under them, slide the PASG under the supine patient, or apply the PASG as if it were a pair of pants. Close and secure the compartments around the patient's lower extremities and abdomen using the Velcro tabs (**Figure 230-5**). Connect the inflation hoses for each compartment to the foot pump. Place a blood pressure cuff on an upper extremity to monitor blood pressure.

The lower extremity compartments should always be inflated prior to the abdominal compartment. The stopcocks must all be closed before inflating any compartment. Open one stopcock at a time to inflate a compartment. Close the stopcock to the abdominal compartment and open the stopcocks to the lower extremities. Inflate the lower extremity compartments using the foot pump. Assess the systemic blood pressure using the blood pressure cuff. **The goal is to achieve a systolic blood pressure of 100 mmHg with the lowest inflation pressure.**² Proceed to inflate the abdominal

FIGURE 230-5. The PASG secured around the patient with Velcro straps.

compartment if the patient still has a blood pressure below 100 mmHg. This blood pressure goal is not important if the PASG is being applied to splint pelvic or lower extremity fractures. **Close off the stopcocks on inflated compartments to prevent deflation.**

PASG DEFLATION

The prehospital-applied PASG can be carefully deflated once under the direct supervision of a receiving physician and increased monitoring and support are instituted. Remove the PASG if a complication develops.

Deflate the compartments gradually. Sudden deflation is equivalent to a significant blood loss.² Blood pressure must be assessed after each compartment is deflated. Deflate the abdominal compartment prior to the lower extremity compartments. Use the stopcocks to achieve the slow and gradual deflation. Prepare and ready intravenous fluids to respond to any decrease in blood pressure.

NASG APPLICATION AND REMOVAL

The application and removal of the NASG is similar to the PASG without the inflation of compartments. Apply the NASG using the Velcro closures. Make sure the abdominal balloon is appropriately placed (**Figure 230-2**). Tighten the abdominal section as necessary to tamponade the bleeding. Removal is easy and does not involve the deflation of compartments. Just undo the Velcro.

COMPLICATIONS

Several complications may occur from the use of a PASG.²³ Its application may prolong scene time when used by poorly trained personnel. Hypotension may occur when garment removal is too rapid. Respiratory distress may be present in the setting of pulmonary edema or diaphragmatic rupture. A compartment syndrome may occur in injured and uninjured lower extremities during prolonged PASG application.^{6,7,10,24} Other complications include renal hypoperfusion, congestive heart failure, vomiting, skin breakdown, lactic acidosis, fluid deficit, and hyperkalemia.^{2,23,25}

The limitations of using a PASG include the limited ability to perform a physical examination, obtain vascular access, and perform any other procedures under the area of the garment. Another consideration is flight transport. PASG compartment pressures have been shown to increase as a function of increasing altitude.²⁶ Adjust compartment pressures during flight.

SUMMARY

The antishock garment may be a useful adjunct to treat traumatic hypovolemic shock and similar conditions. It may help increase venous return, increase systemic vascular resistance, tamponade hemorrhage, and splint fractures. The medical literature is conflicted concerning the device's efficacy. Its use is controversial.²⁷ Complications may occur, especially in the setting of prolonged use. The use of newer devices to treat fractures (i.e., pelvic and femur) and hemorrhage has resulted in less use of the antishock garments.

Hazmat Patient Management

Atilla B. Üner

INTRODUCTION

Hazardous materials (hazmat) incidents occur most often during the transport of chemicals or at industrial site accidents. The work places, transportation, and hazardous substances are labeled with standard government labels or placards (**Figure 231-1**) Hazmat incidents may strike any community at any time.¹ Every Emergency Department must be prepared to respond to victims of a hazmat exposure.

Decontamination is the procedure of eliminating or reducing to a safe level any harmful substances on persons and equipment.² **Decontamination of victims in the field should be performed by Emergency Medical Service (EMS) providers before the patient enters the Emergency Department.** However, this does not always occur. Patients may be too ill for lengthy decontamination procedures prior to transport. Exposed patients may leave the scene and present to the Emergency Department on their own or be transported by EMS using specialized equipment (**Figure 231-2**).³⁻⁸ Basic decontamination by Emergency Department personnel can be safely performed in a designated decontamination area.^{6,9,10}

Exposure to a hazmat-contaminated patient who has been inadequately decontaminated or not decontaminated at all is a real possibility. This can result in exposure and secondary injury to healthcare personnel, other patients, and visitors.⁵⁻⁷ The Emergency Department may be closed in part or in whole until the facility can be decontaminated. The panic and fear induced by rumors or odors can lead to unnecessary facility closure, delayed or inadequate patient treatment, and psychogenic illness in both healthcare personnel and bystanders.^{3,4}

FIGURE 231-2. An example of a containment cell used by EMS. (Courtesy of Quantum EMS.)

The three primary goals for the Emergency Department are to **isolate and contain the contamination; decontaminate and treat exposed patients while protecting staff, other patients, and visitors; and maintain normal services, or reestablish them, as soon as possible.**^{3,11}

Early recognition of potentially hazmat-contaminated patients will aid in preventing secondary contamination and Emergency Department closures. Numerous clues may identify a patient for hazmat contamination at triage.^{3,4} These include accidents at agricultural or industrial sites, accidents involving chemical transports, suspected mass casualty incidents, a cholinergic toxidrome, mucous membrane irritation, chemical burns, soiling with unidentified liquids or powders, intentional overdose with chemicals, unexplained unconsciousness or cardiac arrest, and symptoms occurring in Paramedics or Emergency Medical Technicians (EMTs) after patient transport.

Information management is critical to the response.⁴ Designate a person to obtain as much information as possible on the involved

FIGURE 231-1. An example of the labels and placards used to identify hazardous materials. (Courtesy of www.labelmakers.com.)

substance. Even preliminary and general information is useful and should be immediately conveyed to the treating Emergency Physician.¹ The maintenance of material safety data sheets (MSDS) is mandatory for each chemical used or stored at an industrial site or during transport. Request information on the MSDS from fire department personnel or EMS at the scene. Search for the material's MSDS online. Further information resources are listed after the "References" section of this chapter. Verify all information for accuracy by cross-referencing several sources.⁴

Separate decontamination procedures using diluted bleach for victims of biological weapons agents are no longer recommended for civilian mass casualty incidents.^{6,12} Instead, follow the procedures outlined in this chapter. Most biological warfare agents are transmitted by inhalation; therefore, respiratory protection is highly recommended.

All Emergency Departments should conduct regular in-service training sessions and drills on hazmat decontamination procedures for ambulatory and nonambulatory patients. Personal protective equipment (PPE), including respiratory protection, require regular training for personnel safety and proficiency.¹³⁻¹⁶ Information on decontamination best practices is available from the United States Department of Labor Occupational Safety & Health Administration, the US Department of Homeland Security, the US Department of Health and Human Services, and other resources.^{6,10,17}

This chapter describes a general approach to the management of the hazmat-contaminated patient. The Emergency Department response and patient management will have to be tailored to the specific agent(s) and circumstances, such as the number of patients and facility resources.

ANATOMY AND PATHOPHYSIOLOGY

Hazardous materials can enter the body through inhalation, absorption, and ingestion.¹⁸ The total dose is a function of the concentration and properties of the substance, the exposure time, and the exposure route. There is a dose-response relationship between the absorbed dose and toxic effects for most toxic chemicals, and decontamination is a time-critical medical countermeasure to prevent short- and long-term morbidity and mortality.^{6,7,12,18} The effects can be local, systemic, and quite variable for different agents.

Inhalation is the most common route of exposure. It may lead to local irritation, airway obstruction, and/or pulmonary systemic absorption. Absorption through intact skin is facilitated by fat solubility, open wounds, burns, exposure of the eyes and mucous membranes, and dermal contamination underneath soiled clothing leading to an occlusive dressing effect.^{2,4} The axillae, groin, and skin folds have a thin epidermal layer that facilitates the absorption of a contaminant. Children have a larger surface area to body weight ratio and more permeable skin making them more vulnerable to absorption of toxins.¹⁹ Ingestions can be accidental or intentional.

Patients exposed to hazardous materials can show many signs.⁴ Local effects include chemical burns and respiratory tract effects of inhaled toxins. Systemic effects include those from absorption of toxins, associated trauma, psychiatric reactions (e.g., agitation and anxiety), or contamination without apparent injury.⁴

The hazard to personnel, or risk of secondary contamination, is determined by the dose of the hazardous material that is carried by the victim and absorbed by the caregiver.²⁰ Toxic liquids and solids can pose a dermal contact hazard.³ Solids or volatile liquids can pose an inhalational hazard.³ Most gases or vapors dissipate quickly and are unlikely to pose a secondary contamination hazard.^{6,7,10,20} However, the risk to emergency personnel is real.^{4,5,21,22} Contamination with hazardous materials may indeed cause illness in personnel.^{4,20-22} Toxins can rarely be emitted from vomitus (e.g., hydrogen cyanide

after cyanide salt ingestion) or exhaled breath (e.g., after ethylene oxide exposure).²

INDICATIONS

The decision to initiate decontamination, whom to decontaminate first, and which level of PPE to use must be made according to circumstances and available information.^{6,7} Any patient potentially contaminated with a toxic substance should be decontaminated prior to their entry into the Emergency Department.^{6,21} **Rapid and complete undressing is the most important initial step of decontamination.** Decontamination is a time-sensitive intervention. The more toxic the substance, the more rapidly the decontamination should be performed. Pesticides and corrosives are common and worrisome contaminants.²⁰ Patients requiring immediate medical care, including antidotes, and those displaying signs and symptoms of toxicity should be prioritized. Children and patients with chronic medical conditions should follow those that require immediate care.⁶ Ideally, enough healthcare personnel are present for those requiring immediate care and others that need decontamination before they need immediate care. Initiate any life support measures simultaneously with decontamination.⁴ Patients who have been decontaminated or exposed to gases or vapors without signs of skin or eye irritation may not require further decontamination beyond removal of their clothing.^{2,4,6,9}

Patients should never be made to wait in their contaminated clothing. They need to be given the means to undress in privacy immediately and cover themselves for modesty and protection from the elements.⁶ The next step depends on the nature of the toxic exposure, the number of patients, and condition of the patients.⁶ Self-decontamination occurs by the patient wiping, blotting, or taking a shower in a designated decontamination shower.²³ Patients may need instructions and towels or wipes to self-decontaminate. **Gross decontamination is dealt with by deluge hosing down, showering with water, or using commercial decontamination products. Finally, there is a thorough technical decontamination by hospital personnel.**⁶ Rapid removal of clothing and immediate deluge gross decontamination with water will remove most contaminants and must be instituted without any delay.¹² All three decontamination tiers may be necessary. **Male and female patients should be in separate areas for all stages of decontamination.**

The absence of a system to isolate waste water is not a contraindication to water decontamination.^{6,12} **When in doubt, decontaminate the patient.** Dilution will suffice to reduce the hazardous substance to a safe level.

CONTRAINDICATIONS

Water decontamination may be contraindicated if the risk of hypothermia outweighs the benefit of decontamination, especially in low-risk patients. Alternative approaches such as dry blotting or brushing, the use of chelating agents, the use of an absorbent (e.g., kitty litter), or the use of an adsorbent (e.g., activated charcoal) can be considered.⁶

Contraindications to water decontamination include contamination with calcium, cesium, lithium, metallic sodium, potassium, pure magnesium, rubidium, strontium, sulfur, titanium, uranium, yttrium, zinc, and zirconium.^{1,24} These substances react violently with water and can cause secondary injury.^{1,24} Remove the clothing and gently brush off all visible contaminants followed by covering the patient and/or substance with mineral oil, remove the substance with forceps, and store the substance in a container with mineral oil.^{4,24} However, many of these substances may already have reacted with moisture on the patient's skin.^{1,24,25} Rapid removal of the chemical agent is better than allowing continuing injury to occur.^{9,25} Follow

this by rinsing the patient with copious amounts of water. Adding large amounts of water to the small amount of residual chemical on the patient's body poses little risk of creating a serious reaction hazard.^{25,26}

Patients soaked in flammable liquids pose special problems. Do not cardiovert or defibrillate the patient until the material is completely removed from the skin by water decontamination to prevent an explosion or a fire.⁹

The use of chemical agents for neutralization is contraindicated. These substances may cause secondary injury, toxicity, or react with another substance in an adverse manner. Use large quantities of water for decontamination rather than a neutralization agent.^{6,7,9}

EQUIPMENT

■ PERSONAL PROTECTIVE EQUIPMENT PER PERSON (FIGURES 231-3, 231-4, AND 231-5)

- Scrub suit and closed shoes
- Plastic shoe covers
- Protective goggles
- Water-resistant face mask
- Latex gloves
- Chemical-resistant (i.e., nitrile) gloves
- Chemical-resistant coverall suit with booties and hood
- Duct tape
- Rubber apron
- Butyl rubber gloves
- Chemical-resistant rubber boots or shoe covers
- Respiratory protection (i.e., powered air-purifying respirator [PAPR] with assigned protection factor 1,000)¹⁰
- Skin protectant for hands (optional)

■ PATIENT DECONTAMINATION

- Designated decontamination area
- Decontamination stretchers, if applicable
- Portable wading pools for ambulatory patients
- Tepid running water source with a hose and soft-stream nozzle (50 to 60 PSI water pressure)

FIGURE 231-3. An example of the PPE.

- Portable barriers to assure privacy and protect from wind
- Liquid hand or body soap
- Liquid shampoo
- Soft-bristled brushes or sponges
- Devices to decontaminate hands and nails (e.g., surgical scrub sets)
- Eye irrigation equipment

■ MISCELLANEOUS SUPPLIES

- Polyethylene plastic bags
- Name tags
- Yellow tape and signs to mark decontamination zones
- Shears to cut clothing
- Scrub suits, towels, and blankets for patients before and after decontamination

The Occupational Safety and Health Administration (OSHA) requires level B protection for responders to an unknown chemical hazard with a positive-pressure self-contained breathing apparatus and chemical-resistant clothing.^{3,18,21} The high cost of such equipment and constant skills retraining required to use it may prohibit some hospitals from purchasing it and has made compliance difficult.^{13-16,18} OSHA has published best practice guidelines for hospital-based chemical decontamination procedures including detailed recommendations for PPE.¹⁰

Hospital gowns, standard Tyvek suits, surgical masks, and latex gloves are not considered adequate protection.^{4,6,20,24} PPE is available through specialized dealers and requires training to provide reliable protection.^{4,18,21,24} The minimum protection recommended for hospital decontamination personnel includes a scrub suit, a chemical-resistant suit with booties and hood, plastic shoe covers, at least two layers of gloves (i.e., surgical and nitrile) taped at the sleeve, protective eyewear, and respiratory protection (**Figure 231-3**).^{4,6,10,18} The exact PPE depends upon if the hazardous agent is known, what the hospital has available, and the knowledge of the personnel.

There is little consensus on how to provide respiratory protection. The required level of respiratory protection, if any, will depend upon the agent, the dose, prior training, and decontamination circumstances.^{4,18,21} OSHA has published guidelines under which the use of PAPRs is sufficient.¹⁰ The use of PAPRs requires regular training. Respiratory protection may not be necessary if decontamination is performed outdoors.²⁰ Information obtained about the contaminant will aid in determining the level of protection required.

PATIENT PREPARATION

Patients should be initially received in a secured area outside of the Emergency Department. Clearly mark the area with yellow tape or another similar method. This is considered a contaminated "hot zone." Triage, a primary survey, and any required immediate lifesaving interventions (e.g., basic life support and cardiopulmonary resuscitation) can be performed here by appropriately protected personnel.^{4,18,27} Rapid removal of clothing is essential as absorption is time dependent and contaminated clothing can act as an occlusive dressing or continue to off-gas contaminant.²⁵ **Patients must not wait for decontamination in their contaminated clothing.** Patients who are able should remove their own clothing immediately and be given clean clothing or blankets for warmth and modesty. Children should not be separated from their caregivers if possible.^{19,28}

Patients who present to the Emergency Department with real or imagined contamination are under high stress and are likely to act

out if left unattended.²⁹ The early self-removal of clothing will help alleviate fears and provide a real early decontamination benefit.

The decontamination area is also considered a contaminated “hot zone.”⁴ **Perform basic life support and immediate lifesaving measures only in the decontamination area.**^{11,24} However, the extent of medical treatment in the decontamination area will need to be decided on a case-by-case basis. Treatment of cardiac dysrhythmias and wounds or the administration of toxin-specific antidotes may have to be initiated prior to complete decontamination.^{24,27} Advanced procedures such as endotracheal intubation (Chapter 18), video laryngoscopy (Chapter 20), or venous access (Chapter 61) will be difficult to accomplish while wearing PPE and may have to be supplanted by a supraglottic airway (Chapter 25) or intraosseous access (Chapter 70).³⁰⁻³⁸ **Invasive procedures prior to decontamination may provide a percutaneous route of contamination with the hazardous substance.** Devices (e.g., monitors) used in the decontamination area will need to be decontaminated after use.²⁴ Use long leads, if available, that extend into the clean support area to prevent having to decontaminate monitoring devices.²⁴ **Patients are considered safe to move into the contamination reduction area (“warm zone”) and then the Emergency Department (support area, “cold zone”) only when decontamination is completed.** Perform a secondary survey, including a search for any toxidromes, and begin definitive medical treatment after decontamination.⁴

T

DONNING OF PPE

Putting on PPE is known as donning. Don PPE before approaching the contaminated patient.^{4,10,39,40} This will prevent the healthcare worker from becoming contaminated, now making them a patient, and requiring the healthcare worker to be removed from duty. Suggested minimum PPE and its application is described here (**Figures 231-3 and 231-5**). Face mask and goggles provide splash protection only. An air-purifying respirator (APR) or a PAPR is required for respiratory protection (**Figures 231-3, 231-4, and 231-5**).¹⁰ Information obtained about the contaminant will aid in determining the level of protection required.

Wear standard work attire (e.g., a scrub suit). The application of a skin protectant such as DermostyX (Vitamed Pharmaceutical Industries LTD., Israel) to the hands is optional.⁴¹⁻⁴⁴ The donning of PPE requires the help of an assistant. Put the PPE equipment in one place (**Figure 231-3**).

Assemble the mask power unit (**Figure 231-5A**). Apply the cartridges to the mask power unit (**Figure 231-5A**). Remove any shoes but leave the socks. Put on nitrile gloves (**Figure 231-5B**). Step into the jumpsuit (**Figure 231-5C**). Put on a pair of rubber boots (**Figure 231-5D**). Insert the arms in the jumpsuit (**Figure 231-5E**). Zip the jumpsuit mostly closed (**Figure 231-5F**). Instruct the assistant to hold the mask and attached power unit (**Figure 231-5G**). Place the mask power unit around the waist and cinch the belt

(Figure 231-5H). Instruct the assistant to place the mask on and straighten the collar shields in the front and back (Figures 231-5I and 231-5J). The collar shield is composed of an inner and an outer layer (Figure 231-5K). Instruct the assistant to tuck in the circumference of the inner layer of the collar into the jumpsuit (Figures 231-5L and 231-5M).

Close the zipper on the jumpsuit and secure it (Figure 231-5N). Tighten the neck of the mask so it does not fall off or become disconnected from the jumpsuit (Figure 231-5O). The PPE suit is now on and needs to be secured (Figure 231-5P). Instruct the assistant to apply rubber gloves (Figure 231-5Q). Tape the gloves to the jumpsuit to prevent any material from entering (Figure 231-5R). Use tape specifically designed for this or duct tape. Taping the top of the boots to the jumpsuit is optional but recommended for added safety. It prevents material from getting into the boots and soaking the foot pieces of the jumpsuit. The PPE is now complete (Figures 231-5S and 231-5T).

DECONTAMINATION TECHNIQUE FOR CHEMICAL AGENTS INCLUDING WARFARE AGENTS

Perform a primary survey and treat any life-threatening conditions with basic life support interventions.⁴ Remove all the patient's clothing. This includes shoes and jewelry. **Cutting off clothing will aerosolize less contaminant than pulling off the clothing.**⁶ Place the clothing in a plastic bag and seal it with duct tape. Place this bag into another bag and seal it to "double bag" the clothing. Double bag any jewelry, glasses, hearing aids, keys, and watches separately if time and circumstances permit. This allows for possible later decontamination and salvage. Label the bags with the patient's name or medical record number. In case of a criminal chemical release, these bags may become evidence for law enforcement. Patients may assist with their own decontamination. The patient should keep a form of identification on their person that can withstand the decontamination process (e.g., a laminated driver's license). Patients will object to surrendering their cell phone as it allows them to reach family and may contain telephone numbers that they do not know by heart. Depending on the toxic substance, jewelry, glasses, hearing aids, and cell phones can be later wiped and returned to the patient. For very toxic substances, however, everything on the patient's body must be considered contaminated and may not enter the support zone. **Do not irrigate the patient prior to complete clothing removal.** Chemicals on clothing will soak through wet clothing and onto the skin resulting in additional injury or absorption.^{2,9}

Remove any visible chemicals on the patient's body by gently washing off liquids or brushing off solids. Avoid skin irritation or injury as both will lead to increased absorption of any remaining chemicals. Avoid aerosolization of the contaminant. Blot any heavy liquids with absorbent towels.^{2,9}

Patients with open wounds require the area surrounding the wound to be gently washed with water. Irrigate the wound with clean water. Cover large wounds with plastic wrap to prevent runoff into the wound during the remaining decontamination procedure.² **Do not delay copious water irrigation if this wound care cannot be accomplished rapidly.**

Begin copious water irrigation with high-volume warm water using low water pressure (e.g., 50 to 60 PSI or normal shower pressure) for 3 minutes. Wash with copious water for 1 minute and then clean with soap and water, including the rinse, for 2 minutes. Washing for longer than 3 minutes may soften the skin and lead to increased absorption, a phenomenon called "wash-in effect."^{6,7} Use liquid soap, shampoo, and soft brushes or sponges to gently cleanse the skin and any body hair.⁵ **Do not delay decontamination with**

water if soap is not immediately available as most substances can be removed with water only.⁶ Thoroughly rinse the patient after soaping and shampooing. Repeat the procedure until all visible contamination is removed. **Do not forget to thoroughly clean any mucous membranes, the nails, the external auditory canals, the axillae, the groin, and any other skin folds.** Use cleaning devices such as surgical scrub sets for nail folds or syringes to flush the external auditory canals. Brushes, sponges, or scrub sets must be disposed as hazardous materials and cannot be used on the next patient.⁶

Irrigate the eyes, if contaminated, for 5 minutes (Chapter 187). Remove any contact lenses and discard them. A Morgan lens may be used if the globe is intact. Irrigation with running water is also an option but may be less thorough than **with a Morgan lens. A nasal oxygen cannula may be placed on the bridge** of the nose to irrigate the eyes if both eyes are affected.² Allow water to flow through the cannula and direct it from the medial canthus outward.

Do not let the caregivers carry children in a wet decontamination environment as they may fall and injure themselves and the child. Instead, have decontamination personnel carry the child. It may take two providers to safely carry a struggling wet child while wearing PPE.¹⁹ An alternative is to use a gurney or, wheelchair, or a plastic laundry basket for infants.⁶

The nonambulatory contaminated trauma patient or a patient with altered mental status may need to be decontaminated on a specialized stretcher that is equipped to catch waste water. Autopsy tables from the morgue may be used after covering the surface with plastic. Enough decontamination personnel must be available to maintain cervical spine immobilization while log-rolling the patient as the decontamination process is performed.

ASSESSMENT

Move the patient after decontamination to the contamination reduction zone ("warm zone"). Assess the patient and initiate any required advanced life support measures. **There are no objective criteria to assess whether decontamination was sufficient.** There is, however, evidence that copious water irrigation and soap cleansing are highly effective in removing chemical contaminants.^{4,6} **Successful decontamination can be implied if proper procedures for a given contaminant were followed.**^{4,6} Measure the tear film pH if the eyes were exposed to corrosive agents. Continue eye irrigation until the tear film pH is neutral. This may take up to 15 minutes. Assess all wounds. Thoroughly irrigate any wounds. **Transfer the patient into the support zone (Emergency Department or "cold zone") when they are deemed decontaminated.**

HEALTHCARE PERSONNEL DECONTAMINATION TECHNIQUE

Health-care personnel must remove their personal protective equipment in an organized fashion to prevent self-contamination after decontamination of the patient.^{18,45,46} **Removing PPE is known as doffing.** This is a suggested protocol and may need to be altered depending on institutional policy. Figure 231-6 demonstrates using a plastic bag for doffing. Some institutions use tape on the floor to denote the clear area versus the contaminated area. The use of a plastic bag or a line taped on the floor is institution specific. The main advantage of using a plastic bag is that the contaminated equipment is already bagged without additional personnel touching the contaminated equipment. Doffing, like donning, requires the help of an assistant. The assistant does not need the level of PPE, depending on the substance, that the Emergency Physician requires (Figure 231-6F).

Place the disposable plastic bag on the floor and in the area where the doffing is to take place. Step into the plastic bag (Figure 231-6A

and 231-6B). The rest of the doffing procedure occurs in the confines of the plastic bag. Remove the tape attaching the rubber gloves to the jumpsuit and drop the tape into the bag (Figure 231-6C). Remove the tape attaching the rubber boots to the jumpsuit and drop the tape into the bag. Place the hands between the knees and close the knees (Figure 231-6D). Pull the hands upward and out of the rubber gloves (Figure 231-6E). Open the knees and let the contaminated rubber gloves fall into the bag. Stand upright. Instruct the assistant to grasp and hold the mask power unit (Figure 231-6F). Remove the mask power unit (Figure 231-6G).

Prepare to remove the mask. Loosen the neck of the mask (Figure 231-6H). Unzip the jumpsuit (Figure 231-6I). Remove the arms of the jumpsuit (Figures 231-6J and 231-6K). Push down the jumpsuit while only touching the inside. Step out of the jumpsuit and one boot (Figure 231-6L). Move the free leg out of the bag (Figure 231-6M). Remove the other leg from the jumpsuit and boot and place this outside the bag (Figure 231-6M). Bend forward (Figure 231-6N). Remove the mask (Figure 231-6O). Place the mask in the bag (Figure 231-6P). Instruct the assistant to place the power unit they are still holding into the bag (Figure 231-6Q). Remove the nitrile gloves (Figure 231-6R) and place them in the bag.

Instruct the assistant to seal the bag with duct tape.⁴⁷ Close off the dirty area until the level of contamination is established and the area

is properly decontaminated. Move to a shower area. Shower thoroughly with soap and water. Dress in normal work attire.

AFTERCARE

Further patient management will depend on the type of exposure and other circumstances. Perform a thorough secondary survey to detect occult trauma or medical illness. Monitoring for cardiac dysrhythmias or for noncardiogenic pulmonary edema may be necessary after exposure to certain chemicals.^{2,9} Some toxins necessitate treatment with specific antidotes which should be initiated as soon as possible.^{48,49}

Dilute ingested chemicals with 4 to 8 ounces of water. Activated charcoal at 1 gm/kg may be given to prevent further absorption.⁹ Ingestion of corrosive agents may necessitate early endoscopy, in which case charcoal should be withheld.⁹ **Induction of emesis is rarely indicated.** Emesis may pose a hazard to the patient if they ingested corrosives or hydrocarbons and to healthcare personnel if the patient ingested cyanide.^{2,9}

COMPLICATIONS

Hypothermia may be caused or worsened by the decontamination procedures.^{2,9} This must be anticipated and treated accordingly. Children are especially vulnerable to hypothermia.^{10,28} Residues of

highly toxic chemicals remaining in skin folds or under nails may pose a risk to the patient and caregivers.⁹ This should be searched for and removed. Toxic vomitus may pose a risk to healthcare personnel, even after adequate decontamination.^{2,9} Emesis must be contained and discarded appropriately.

Decontamination personnel are subject to dehydration, exhaustion, heat illness, and hyperthermia exhaustion while wearing PPE. Work cycles need to be adjusted to maintain personnel safety. The improper use of PPE can result in contamination of the healthcare personnel.⁵⁰ Frequent drills will prevent this from occurring.

SUMMARY

Emergency Departments must be prepared to decontaminate and treat victims of hazardous materials exposures at any time. Procedures must be developed, practiced, and incorporated into the hospital's mass casualty incident plan. Lack of preparation and practice will expose medical personnel to greater risks and lead to less than optimal patient care. This chapter presents a general approach to decontamination procedures that must be adapted to the individual circumstances and type of exposure.

Physical Restraints

Dean Sagun

INTRODUCTION

Psychiatric emergency services have become a major point of entry into the mental health system and a principal treatment site for many patients with chronic and severe mental illness.¹ Emergency Department (ED) patients with altered mental status, emotional disturbances, head trauma, psychiatric illness, psychological disturbances, or other medical conditions may be aggressive, physically injurious, or violent.^{2,3} The aggression may be exhibited toward themselves or toward the healthcare personnel who are caring for them.⁴ **Emergency Physicians must be prepared to cope effectively with agitated or violent patients to reduce the risk of serious injury to the patient and healthcare personnel. Physical restraints might be necessary to ensure the safety of the patient and the healthcare personnel given the volatile nature of some presenting conditions.** A prospective study found that 0.07% of ED patients were restrained during the 1-year study period.⁵ Up to 8.5% of psychiatric patients seen in the ED may require the use of physical restraints.⁶ Most patients were restrained for agitation, disruptive behavior, or violent behavior.^{5,6}

Physical restraints are the direct application of physical force to a patient without the patient's consent to restrict their freedom of movement. The use of restraints for managing behavioral emergencies is allowed only when all other less restrictive measures have failed and severely aggressive or destructive behaviors place the patient or others in imminent danger. The Centers for Medicare and Medicaid Services (CMS) defines physical restraint as "any manual method, physical or mechanical device, material or equipment attached or adjacent to the patient's body that he or she cannot remove and that restricts freedom of movement or normal access to one's body."⁷ The use of restraints in the ED may help to prevent patients from physically harming themselves or others. Imminent safety concerns are the only justification for application of physical restraints.⁷ Physical restraints must be used for the shortest time possible and with the least restriction possible.^{7,8} Physical restraints are humane and effective in the management and treatment of the patient while ensuring the safety of the patient and the health-care personnel if used properly and in the appropriate patient.

This chapter will present the rationale and technique for using locked-door seclusion and physical restraints in the ED. This chapter focuses on the aggressive, dangerous, and/or violent patient. It briefly reviews some of the techniques for physically restraining the young child during brief diagnostic or therapeutic procedures.

LEGAL CONSIDERATIONS

Informed consent is required before Emergency Physicians can lawfully treat competent adult patients, all of whom have the right to refuse medical treatment (Chapter 1). U.S. courts have consistently upheld the idea that a competent adult would consent to treatment to maintain health or life and that a patient could be restrained to protect others or self if the reasons for interventions are clearly documented.⁹ **The competent adult retains their right to refuse treatment in an emergency setting. Coercive measures (e.g., restraints and the threat of restraints) cannot be used solely because a patient refuses treatment. It is never appropriate to restrain a competent patient against their will solely because they are refusing recommended treatment.¹⁰** The CMS, which governs

hospitals, have required specific training elements for personnel who will be applying physical restraints. They require hospitals to have clearly delineated policies as to who is certified as capable of applying restraints. The elements of training include the use of non-physical interventions and the demonstration of these skills.

INITIAL APPROACH TO THE PATIENT

Evaluation of the combative patient begins with a risk assessment and attention to safety measures. Assess for potentially dangerous organic causes of agitation when this can be done safely. Alcohol intoxication, drug intoxication, and substance withdrawal are common diagnoses in combative patients. Obtain a fingerstick glucose and complete set of vital signs. The typical patient first becomes angry, then resists authority, and finally becomes confrontational. **Signs of impending violence include aggressive acts, an angry demeanor, pacing, provocative behavior, speech that is aggressive and loud, and tense posturing.**

There are many risk factors for violence.¹¹ Young age and male sex are common characteristics in many violent patients. There is often current substance abuse, a history of substance abuse, or a history of violence. Patients with psychiatric disorders can be violent. Low socioeconomic status is associated with violence. The environment of the ED is associated with violence in some cases. This includes crowding, lack of privacy, and prolonged stays.

Use verbal de-escalation techniques prior to initiating physical restraints (Table 232-1).¹² This approach can assist the Emergency Physician in engaging the patient and calming the situation. Patients who are agitated but cooperative may be amenable to this approach. Carry out all techniques in a calm voice that is clear, slow, and low in volume. Use an attentive, nonconfrontational, and receptive manner without conveying vulnerability or weakness. Stand at least two arm's lengths away from the patient with direct access to the door or exit. Avoid approaching the patient from behind or moving suddenly. Gently question the patient as to why they are distressed. Allow the patient time to think about the question prior to offering an array of potential choices. Common reasons why ED patients become agitated include being frightened in a medical facility, being frustrated at the perceived lack of concern on the part of healthcare providers, being hungry, being made to undress and put on hospital attire, being in pain that they do not feel is being promptly addressed, and not understanding why things are happening. **Addressing the patient's specific concern can often de-escalate the agitated patient.**

Begin to orient the patient to their environment if they are unable to communicate their needs or are too agitated to tolerate questioning. Explain in clear language what needs to occur. For example, "Mr. Smith, you are in the ED because you are having a fever and we now need to get you dressed in a hospital gown. Can you do that for me? May I help you?" **Allow the patient some control to**

make decisions about the sequence of events as safety permits. For example, if the patient first wants to use the restroom or drink water, allow the patient to do these things first. Patients who are confused or frightened often de-escalate with these techniques.

It is often possible to encourage the patient to take oral or intramuscular medication prior to the use of physical restraints. The ability to begin a patient on needed medical treatment (i.e., benzodiazepines for alcohol withdrawal or antipsychotic agents for paranoia) may allow the patient to de-escalate and eliminate the need to initiate physical restraint. Carefully monitor the patient including constant observation, pulse oximetry, telemetry if appropriate, and vital signs at regular intervals.

INDICATIONS

Restraints are an emergent or urgent intervention when less restrictive interventions have failed.¹² Use restraints for patients who are currently demonstrating behaviors that would put them, the staff, or others in imminent danger.¹² This includes patients who are aggressive, agitated, combative, dangerous to self or staff, or violent and do not de-escalate with other interventions. **Do not delay using restraints if patients can harm themselves or others. The use of physical restraints is a last resort.**^{13,14}

CONTRAINDICATIONS

Do not use physical restraints for the sake of convenience or if a competent adult refuses treatment. Do not use them for patients who are currently not demonstrating behaviors that would put them, the staff, or others in imminent danger. Patients with a history of violence but exhibiting no active imminent aggression cannot be restrained. The use of physical restraints is an urgent intervention when less restrictive interventions have failed.¹²

Physical restraints must be immediately released when the patient is no longer demonstrating dangerous behavior. There are potentially severe complications associated with the use of physical restraints. Hospitals must ensure appropriate staffing levels to meet this dynamic need. Every acute care hospital has developed policies and procedures for the monitoring and documentation associated with the use of physical restraints. A sample of the required documentation can be found in Table 232-2. The Emergency Physician must be cognizant of these requirements and be able to follow these policies and procedures. Asphyxiation and strangulation are the two most serious complications of physical restraint.¹⁵ Personnel must be available to continuously monitor the patients' respiratory status throughout the application of physical restraints.

The use of leather restraints significantly increases the risk of neurovascular complications, rhabdomyolysis, and skin breakdown even when used correctly. Patients should demonstrate the ability to break free from soft restraints or require the additional security of leather restraints prior to application of leather restraints. **Leather restraints are to be considered a restraint of last resort.**

Do not use seclusion if the patient is unstable, if the patient must be medically monitored, or if they overdosed on medications and/or poisons. **Seclusion is contraindicated if the patient cannot be constantly monitored visually, either electronically with closed-circuit video or by direct observation.**

EQUIPMENT

- Gloves
- Additional personal protective equipment, if indicated
 - Gown
 - Face mask with an eye shield or goggles
 - Cap

TABLE 232-1 Key Elements for Verbal De-Escalation³⁵

1. Respect personal space (e.g., maintain two arm's lengths and provide space for an easy exit)
2. Do not be provocative (e.g., stay relaxed and do not stare at the patient)
3. Establish verbal contact (e.g., the first person to contact the patient should be the leader)
4. Use concise and simple language
5. Identify feelings and desires
6. Listen closely to what the patient is saying to improve the mutual understanding
7. Agree or agree to disagree
8. Lay down the law and set clear limits (e.g., violence and abuse will not be tolerated)
9. Offer choices and optimism
10. Debrief the patient and staff

TABLE 232-2 Typical Documentation Requirements for the Physical Restraint of a Patient

Physician Orders
<ul style="list-style-type: none">• Date and time of order• Alternatives to restraint employed (i.e., verbal de-escalation)• Description of specific behavior that placed patient, staff, or others in imminent danger• Patient response to alternatives• Type of restraints and which limbs to restrain
Ongoing Assessment
<ul style="list-style-type: none">• Description of behaviors that patient needs to demonstrate to release restraints• Documentation of personnel involved in the application of restraint, including security and other trained staff• Existence of an emergency• Failure of less invasive techniques and list them• Family notification of restraint as appropriate• Injury from restraints and treatment• Patient's preexisting medical or psychiatric condition that may increase the risk of harm• Patient's reaction to restraints• Reason for using restraints was/is explained to the patient• Use of restraints was for patient benefit, patient safety, or staff safety
Conclusion of Restraint
<ul style="list-style-type: none">• Debriefing of the patient regarding the episode of restraints including their reaction to the application of restraints• Debriefing of the staff as appropriate• Discontinuation of the restraint order• Documentation of the expected behavior demonstrated by the patient that led to release of restraints and current behavior

- Standard ED bed
- Hospital-approved restraint devices
- Philadelphia collar, various sizes
- Additional personnel

The following equipment may be necessary for putting a patient in physical restraints. Utilize personal protective equipment (PPE) if contact with the patient's body fluids may occur. **Use only devices manufactured for the express purpose of restraining a patient.** Restraints are available in a variety of styles. They are made of many materials (e.g., leather, material, polypropylene, and polyurethane) with Velcro or buckles to secure them. Use a standard ED bed for two-point and four-point restraints. Use padding material to protect the patient's bony prominences. Soft restraint manufacturers usually include this already attached to the restraint. Leather restraints are physically stronger and less constricting than soft restraints. **Leather restraints are more effective in the violent patient than soft restraints.**

Makeshift restraints (i.e., gauze rolls) are difficult to apply and must be tied extremely tightly to secure the patient. **Avoid makeshift restraints in the ED because of the increased risk for injury to the skin, peripheral nerves, and vasculature.** Makeshift restraints can cause respiratory difficulties if placed around the chest.

PREPARATION

Appropriate use of restraints requires prior planning and education of physicians, nurses, and security staff. Physical restraints may pose a danger to the patient and the staff without sufficient training and safeguards.^{2,16} The Emergency Physician must provide a timely diagnosis and an appropriate acute management plan to ensure the safety of a patient and the staff. **The “ABCs” of the emergency evaluation of aggressive and impulsive behavior include safety, diagnosis, and management. Safety is the first priority when confronted by a potentially violent patient.** Adequate evaluation,

diagnosis, and management are impossible without proper safety mechanisms.

The application of physical restraints requires the understanding that physical restraints are mechanical devices that prevent patient interference with medical treatment, reduce the risk for falls and subsequent injury, and/or keep the patient from harming themselves or others. **Use physical restraints as a last resort for maintaining patient safety. Continually evaluate the alternatives to physical restraints.** It is important to be familiar with hospital procedures for ordering physical restraints, including documentation requirements (Table 232-2).

The Emergency Physician must understand the indications and purposes for use of the different types of restraints and their respective functions (e.g., wrist restraints to prevent arm movement). Observe and document the type of behavior that has led to the need for physical restraint (e.g., attempting to harm oneself or others, removing intravenous (IV) catheters, or removing other equipment) and the type of restraint prescribed (Table 232-2). An Emergency Physician order for physical restraint is required and must be documented within 1 hour of the application of the restraints (Table 232-2). It can be documented after the restraints are initiated. The treatment team (i.e., Emergency Physician and nursing) should each document the situation, the alternatives to physical restraint that were attempted, and that alternatives were attempted with lack of success. Review the manufacturer's directions for assembling and placing the physical restraint. Lower the bed as low to the floor as possible. Visually inspect the bed to ensure it is free of objects that may be trapped under a physically restrained patient.

The restraints, sufficient number of personnel, and a plan should be assembled and ready prior to initiating physical contact with the patient. This will reduce the risk of asphyxiation or other complications due to a prolonged physical contact time with the patient. All personnel must be approved for applying restraints to protect the patient and the staff. At least one of the staff members should be a female if the patient is female. It is best to have security standing ready to assist if needed. Their mere presence and visibility to the patient as a “show of force” is often enough to calm the patient. Emerging practices may include a scribe to document the initiation of restraint and to ensure the safety of the patient during the application of restraints by keeping time, monitoring the patient's status, and confirming respirations.

One or two people will usually be physically applying the restraints. It is common to need up to four additional personnel to hold the patient during the application of the restraints. Understanding the nature of the aggressive behavior and the physicality of the person who will need to be restrained may help determine how many additional personnel are required. **It is always better to have more people than needed than to not have enough. It is dangerous for the patient and the staff to have fewer people available to help than are needed. It is often better to have a “show of force” with multiple staff members and security present to be visible to the patient. The mere presence of multiple people conveys the message you are serious, often makes the patient more compliant, and gives the patient an excuse to cooperate with the application of physical restraints.** The application of physical restraints is time limited and is a personnel-intensive process. Be aware that other agitated patients may take this opportunity to elope from the facility.

Communicate with the patient and family. Evaluate whether the patient or family members require special considerations regarding communication (e.g., deafness, illiteracy, or language barriers). Arrange to meet these special needs if necessary. Briefly assess the patient and family for knowledge deficits and anxiety regarding the physical restraint procedure. Assign a staff member to provide information and emotional support as needed.

Family members should not be present for the physical restraint procedure. They may become agitated during the procedure and make it an unsafe environment for staff. They may serve as an agitating influence on the patient. All family should be politely asked and escorted to wait in the lobby or family room until the patient is secure. Inform the family that they may return once the patient is restrained and any procedures have been completed. Inform the family members that under no circumstances should they loosen or remove the physical restraints as this should be done solely by hospital staff.

All staff involved must have a knowledge of proper patient positioning.^{12,13} **Attempt to not restrain a patient with one or both arms positioned above their shoulders. These “arm-elevated” positions can result in respiratory compromise. Restrain the patient in the supine position with their arms by their sides. The restraints must always be tied to the bed frame and not the side rails.**¹⁷ The patient can experience significant pain and injuries if the bed rails are lowered while the restraints are tied to them.

TECHNIQUES

LOCKED-DOOR SECLUSION

One form of physical restraint is locked-door seclusion (LDS). **LDS provides a low-stimulus environment that is free of dangerous objects. It is a less restrictive form of physical restraint that is an appropriate and viable alternative if the patient is more likely to be an escape risk, dangerous to others, or dangerous to themselves.** Patients who are violent or self-destructive may be placed in LDS. Agitated patients can be placed in LDS by security that are authorized and trained to physically escort patients. A “show of force” often makes the patient more cooperative. ED staff can assist a patient who is not physically threatening but for whom the regular ED environment provides too much stimulation to allow effective treatment to occur. Have security present to prevent injury to the patient or the staff. Agitated patients may require that all treatment, including changing into hospital attire, commence in the LDS setting.

Hospitals who have LDS capability should have built the room according to The Joint Commission (TJC) parameters to provide safety, reduce stimulation, and lessen the risk of self-injury. These rooms have very limited equipment and supplies other than a bed so that the patient does not injure themselves. A patient can inflict significant self-injury with simple things (e.g., blood collection tubes, needles, and tongue depressors). **The LDS room must be continuously monitored via video or direct 1:1 monitoring.** State laws and institutional policies vary on what type of monitoring and documentation are required. **It is important to recognize that a patient is not absolutely safe in LDS.** Highly agitated patients can injure themselves.

The most likely cause of death in LDS is a cardiac event. It is especially important that a physical examination proceed as rapidly as possible after the patient is placed in LDS to address and correct any underlying causes of aggression and/or agitation (e.g., head trauma, hyperglycemia, hypoglycemia, and hypoxia).

PHYSICAL RESTRAINTS

Perform hand hygiene and apply personal protective equipment as needed. **Introduce yourself and your plan to the patient in a calm manner.** Assemble all the required personnel in the room. Provide privacy by closing the door to the room and/or pulling the curtain around the patient's bed if in a shared patient room.

Do not physically participate in holding the patient or the application of physical restraints. This allows the Emergency

Physician to maintain the physician-patient relationship required to subsequently evaluate, manage, and treat the patient. Trained staff should physically assist the patient into a comfortable supine position that allows easy access to the area of the body to which the restraint will be applied. It may help to have a team member to hold and lock the patient's elbow or knee in extension. Apply the soft restraints to the patient's wrists and leave approximately 1 to 2 cm between their wrist and the restraint. It should fit snugly but not constrict (**Figure 232-1**).

Apply and tie the two long ends or strapping to the bed frame as a unit (**Figure 232-2**). Attach the ties to the portion of the frame that moves when the head of the bed is raised and lowered. **Do not attach the ties to the side rails.** Attaching the restraint ties to the side rails increases the patient's risk for injury when the side rails are moved down or up. Make a slip knot with the ties (**Figure 232-2**). The slip knot is easily released by pulling on the free ends of the ties (**Figure 232-3**). This allows for easy removal in case of an emergency. Secure the restraints to the bed frame in such a manner that both wrists remain at the patient's sides to reduce shoulder injury risk. **Use caution restraining the patient with one or both arms**

above their shoulders to ensure that the patient does not experience respiratory compromise (Figure 232-4). Avoid the prone or hobble restraint position (i.e., arms and legs restrained behind the patient) as this can result in respiratory complications.

FIGURE 232-3. Pulling the loose ends of the soft restraint will immediately release the knot.

The two-point soft restraint of the wrists is less restrictive than the four-point restraint of all limbs. Apply the four-point restraints to both wrists and ankles. Apply the soft restraints to the patient's ankles like that of the wrists. Leave approximately 1 to 2 cm between the ankle and the restraint (Figure 232-5). They are attached to the bed frame.

Soft restraints are less restrictive than leather restraints (Figure 232-6). The method for determining which type of restraint is required must be determined by clinical experience and the current situation involving the patient and their behavior. Patients who are physically frail and nonviolent may benefit from two-point soft restraints. Use of four-point restraints may be necessary for patient safety if they are able to move too freely and are agitated.¹² Severely agitated, aggressive, and dangerous patients may require leather restraints. **The goal is to utilize the least restrictive restraint method while ensuring the safety of the patient and the staff.**

FIGURE 232-4. A restrained patient using four-point restraints and one arm elevated.

FIGURE 232-5. Soft ankle restraints should have a gap of one to two finger breadths between the patient's ankle and the restraint when applied.

Other restraint devices have been used in conjunction with extremity restraints (**Figures 232-7 and 232-8**). Apply a Philadelphia cervical collar to minimize the potential for biting and head banging. An alternative that is more readily available in the ED is to apply a standard cervical collar that is used for the trauma victim. Exchange the standard cervical collar as soon as possible with the softer Philadelphia collar to prevent the standard collar from injuring the patient. **Never use a torso restraint or sheet around the torso.** Limiting chest movement and respirations can result in respiratory compromise and death. Use a device specifically designed to be wrapped around the patient's hips and that attaches to the bed frame (**Figure 232-7**). Consider the use of a net restraint in the very agitated patient who cannot be de-escalated (**Figure 232-8**). Chemical restraint can be safely administered once the patient is physically restrained (Chapter 233).

PEDIATRIC PATIENTS

Pediatric patients are rarely restrained for aggressive and violent behavior. The very young are commonly restrained for diagnostic and therapeutic procedures (**Figures 232-9 and 232-10**).¹⁸⁻²⁰ These are brief episodes of discrete restraint for specific indications. Use the same general indications, contraindications, and concerns with children as an adult. **Do not place young children in LDS by themselves.** This can result in them becoming more frightened and agitated. Allow the parent or guardian to remain in the LDS room if it is safe for them to do so. Some states have passed strict guidelines for using physical restraints on mentally and physically handicapped children.

FIGURE 232-7. A hip restraint added to the four-point restrained patient. (Photo courtesy of Posey Products LLC, Arcadia, CA.)

A popular device is the papoose board for restraint. There are several companies that make restraint boards. These are temporary devices to be used during procedures and are commonly used (**Figure 232-10**). They come in neonatal through adult sizes. Restraining boards usually include canvas flaps that are strong with Velcro fasteners. They are easy and simple to clean after use. They can be configured for various procedures (**Figure 232-10C**). This includes arm extenders, straps for arms, and straps for the head.

The procedure is technically the same for pediatric patients who require physical restraint for aggressive and violent behavior.¹⁹ The restraint time requirements are different. Limit the time an adult is physically restrained or in seclusion to 4 hours. Physical restraints and seclusion must be limited by decreased time intervals in pediatric patients: 2 hours for children and adolescents ages 9 to 17 and 1 hour for patients under 9 years old. Document an assessment and a new order for the continued use of physical restraints or seclusion after this time. Release the restraints every 1 to 2 hours, assist the patient to the bathroom, and offer food and fluids as appropriate in older children.¹⁷ It is wise to document patient assessments at more frequent intervals than with an adult. Follow hospital policies regarding documentation and assessments.

FIGURE 232-8. The net restraint. (Photo courtesy of Posey Products LLC, Arcadia, CA.)

FIGURE 232-9. The Olympic Circumstraint Neonatal Immobilizer.

Frightened young children not able to respond rationally to their circumstances may be soothed when held by an adult which is termed therapeutic holding. This helps the pediatric patient regain control of their emotions, is an alternative to mechanical restraint, and is an alternative to seclusion.^{2,21-25} Restraint is considered part of ongoing care if it is used for procedures. This requires specific training beyond the scope of this chapter. Adolescents may need to be separated from friends or family members who are causing their behaviors to escalate.

ASSESSMENT

Patients who are restrained require constant observation by specifically trained personnel. The complication rate for a patient in physical restraints has been estimated at 5.4% to 7%.^{5,24} Evaluate the patient every 15 minutes for signs of injury or according to hospital protocol for the type of restraint. Documentation of monitoring includes confirming airway patency, breathing, and circulation. Monitor IV catheters, urinary catheters, drainage tubes, and other equipment at regular intervals to verify correct positioning and the absence of occlusion by the restraints. Assess the needs of the patient and/or family members. Offer additional information and emotional support as needed. **Continually assess whether restraint of the patient is necessary.** Evaluate the appropriateness of restraint use, including the level and characteristics of the patient's activity, at least once every 4 hours. Note whether the patient continues to exhibit the behaviors (e.g., agitation, combativeness) that have made restraint necessary. **The treating Emergency Physician must perform and document a face-to-face evaluation of the patient within 1 hour of the application of physical restraints.**¹⁷ Provide written information as appropriate to reinforce patient and family teaching. Document the procedure in the patient's medical record. Include all teaching and the need for any follow-up education.

Patients will need to be continuously monitored if they are restrained secondary to violent and self-destructive behaviors. State

FIGURE 232-10. The Olympic Papoose Board. **A.** The device. **B.** A child restrained. **C.** Numerous configurations of the Papoose Board. (Photo courtesy of Natus Medical Inc., Pleasanton, CA.)

laws vary on monitoring if the patient is placed in restraints for non-violent and non-self-destructive behavior. They may be monitored less frequently. Hospital policies determine these parameters so that they meet legal, TJC, and CMS requirements.

AFTERCARE

Take an organized approach to remove the restraints once the patient has calmed down. Talk with the patient about removing the restraints and review the patient's ability to stay calm and follow instructions. This process is known as debriefing.¹⁷ Some Emergency Physicians release all restraints at once.

Releasing the restraints in a stepwise approach may prove safer. Release one of the patient's arms. Inform the patient that if they remain calm the other restraints will be removed. **Observe the patient to ensure that they do not release their other restraints once an arm is free.** Wait a short period of time before releasing the opposite arm if in two-point restraints or their opposite leg if they are in four-point restraints. Wait a short period of time if the patient was in four-point restraints before releasing the remaining two restraints at the same time. An alternative in the four-point restrained patient is to initially remove both leg restraints followed by one arm then the other.

Never leave the patient with only one arm restrained without a staff member at the bedside. This allows too much mobility and may cause harm to the patient and the staff members if the patient becomes combative or falls from the bed.² Never leave a patient restrained only by their legs as they can become injured if they fall off the bed.

Discuss with the patient the reason restraints were required.²⁶ Include in the discussion the alternatives that were first tried and that failed thus requiring physical restraint. Review the behaviors that should be avoided in the future that will prevent the application of physical restraints. Ensure that basic needs (e.g., diet, hydration, and toileting) are met for any patient restrained.

COMPLICATIONS

The use of physical restraints can result in asphyxia, strangulation, and sudden death if they are incorrectly applied or if the patient is not appropriately monitored.²⁷⁻³¹ Patients restrained in the prone position or who are under the influence of stimulants are at an increased risk of complications.³²⁻³⁴ **Never restrain a patient in the prone position as this can compromise their respiratory function.** Tightly applied restraints or the patient fighting against the restraints can result in abrasions, contusions, extremity fractures, joint dislocations, neurovascular damage, rhabdomyolysis leading to acute renal failure, or skin breakdown.² Consider the use of chemical restraint (Chapter 233) to minimize these potential complications and to be able to release the physical restraints.

DOCUMENTATION

Thorough documentation of the incidents involving the use of restrictive physical intervention is essential (Table 232-2).¹² No single set of documentation guidelines has been drawn up to define what exactly to record after such incidents have occurred.²⁴ The documentation standards for restraint and seclusion episodes include circumstances leading to use, monitoring requirements, and staff debriefing.

SUMMARY

Patient violence occurs in many clinical settings and Emergency Physicians must be prepared to cope effectively with agitated patients to reduce the risk of serious injury to the patient and staff. On occasion, patients display behavioral disturbances that create an imminent danger for themselves and others. Alternatives to physical restraint including verbal de-escalation techniques must be attempted and documented before the initiation of physical restraints. It is necessary at times to physically restrain a person to facilitate their diagnosis, facilitate treatment, and prevent injury to the patient and medical staff. Every restrained patient must be carefully and frequently monitored. Remove physical restraints as soon as possible after reassessment.

Chemical Restraint

David K. Duong and Dara Mendelsohn

INTRODUCTION

Acute agitation, psychosis, and violent behavior are common presentations in the Emergency Department (ED) and pose a threat to patients and the staff caring for them.¹⁻⁴ Management of the agitated patient presents a complex challenge of minimizing the risk of potential violence while enabling appropriate clinical evaluation of the agitated state. The underlying diagnosis is often unknown and treatment must often be rendered urgently with limited time for decision making. Such presentations can interfere with the ED evaluation and treatment as well as compromise both patient and staff safety. These behavioral emergencies may require pharmacologic intervention to reduce agitation, resume a more normal physician-patient relation, and facilitate safety (Figure 233-1).

The use of chemical restraint implies that medications are used to control behavior and confine a patient's bodily movement without an assessment and treatment plan.⁵ This is rarely the case in the ED as medications to manage behavioral emergencies are administered as part of an evaluation and plan of care. **The Emergency Physician (EP) is addressing the medical emergency of agitation and violence in the patient and starting the treatment.** While the phrase "chemical sedation for acute agitation" may be more appropriate, for the purposes of this chapter, the phrase "chemical restraint" will refer to the emergent use of medications to control dangerous behavior in a patient. **Do not use the phrase "chemical restraint" on your charting.** This phrase sets off red flags among personnel from hospital administration, utilization management, and outside official review organizations.

GENERAL CONSIDERATIONS

Behavioral emergencies provide complicated medical and ethical considerations. The benefits of chemical restraint should be seriously considered against the potential side effects of the medication. The EP must be aware of alternatives to chemical restraint as well as the careful assessment, reevaluation, and treatment of the acutely agitated patient. Chemical restraint ideally provides a calming, rather than sedating, effect with a continued emphasis on doing no harm to the patient while simultaneously reducing the risk of violence.^{6,7} An objectively good response to chemical restraint may still leave the patient feeling traumatized and angered. **Allow the patient to participate in treatment decisions to the extent possible.** This can be achieved through simple tasks such as asking the patient if they have a medication preference or offering a choice between potential medications.⁷ **Attempt further verbal de-escalation or a "show of force" before applying any physical or chemical restraint (Figure 233-1).**⁸⁻¹²

EDs should have written policies regarding restraint use and monitoring as mandated by the Centers for Medicare and Medicaid Services (CMS) and The Joint Commission (TJC).^{5,13,14} Both CMS and TJC have guidelines for the use of restraints. **The CMS defines chemical restraint as use of any medication to restrict a patient's behavior or freedom of movement but is not the standard treatment or dosage for the patient's underlying condition and strongly cautions against its use for discipline or medical staff convenience.** The CMS and TJC recognize the legitimate use of restraint for the protection of the immediate physical safety of the patient and staff. Both organizations identify restrictions

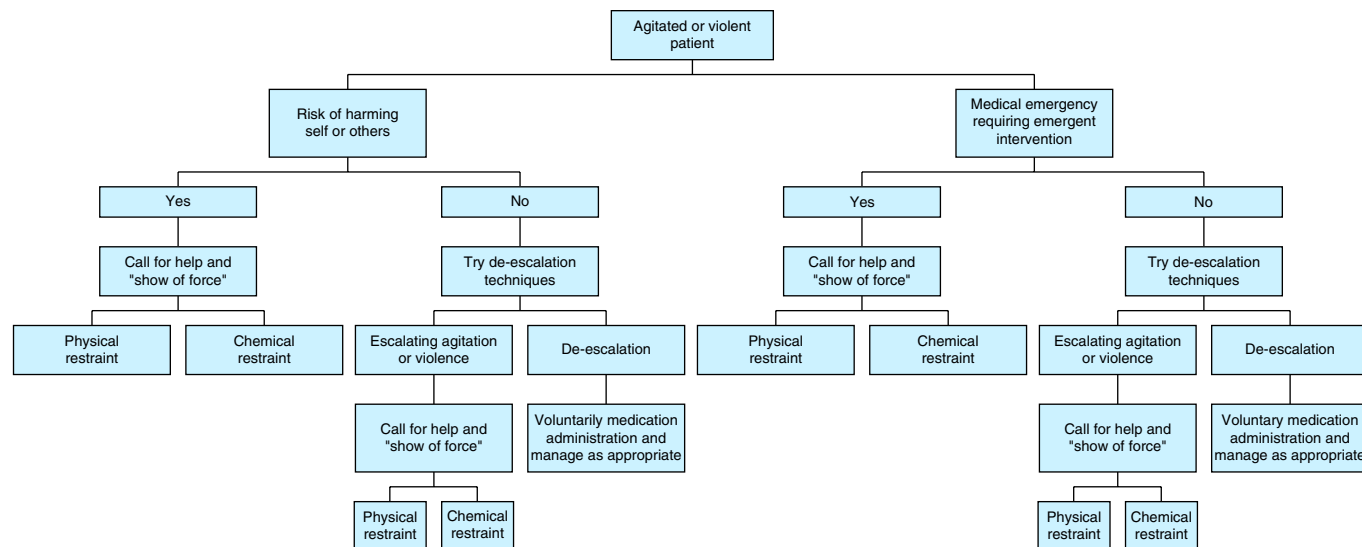

FIGURE 233-1. The management of the agitated or violent patient in the ED.

including that restraints must only be used when less invasive interventions have failed; must be ordered by a licensed clinician (i.e., can be a nonphysician); require the patient to be evaluated by a physician as soon as possible (but must be done within 1 hour); and cannot be written as a standing or as needed order.^{5,9,15-17}

A brief consideration of the legal and ethical implications of chemical restraint deserves mention. Consent for evaluation and care is implied during an emergency. The courts assume a competent lucid adult would consent to treatment necessary to maintain health or life.¹⁸ The EP must consider whether the patient has the decisional capacity to refuse offered care. The EP should feel comfortable in the treatment of life-threatening emergencies. It is best to err in favor of treatment if there is doubt to the competency of the nonconsenting patient.¹⁸ Some leeway must be given to patient preference for treatment if the patient is competent. The EP must document their thought process and justification for administering chemical restraint. The covert administration of chemical restraint may be problematic and no universal ethical standard has been established in an ED setting.^{19,20} It is advisable to review the ED and hospital restraint protocols that have been vetted through the hospital administration and legal review.

INDICATIONS

There is no precise definition of clinical agitation or violent behavior in the ED that necessitates chemical restraint.²¹ Experts have agreed that explosive and/or unpredictable anger, intimidating behavior, restlessness, pacing, excessive movement, physical and/or verbal self-abusiveness, demeaning or hostile verbal behavior, and impulsive or impatient behavior are components of clinically significant agitation.^{7,22} A history of violence regardless of diagnosis, male sex, drug abuse, substance abuse, and alcohol abuse are associated with violent behavior (Table 233-1).^{18,21-24} However, there is no reliable way to clinically predict which patients will be imminently violent.²² The history and physical examination will usually determine which patients are agitated, violent, or have imminently violent potential. Verbally engage the patient to the extent possible to obtain preliminary information and assess their potential for verbal de-escalation. The patient should ideally be asked about their intent to harm themselves or others, if they possess a weapon (e.g., on their person or at home), a history of recent violence, current alcohol or illicit drug use, medical conditions, and psychiatric conditions. The possibility of violence should be taken seriously and acted upon quickly.

TABLE 233-1 Causes of Agitation

Infectious	Medications and toxicology		Metabolic	Neurologic	Psychiatric	
Brain abscess	Adrenergics	Gamma-hydroxybutyrate	Acute intermittent porphyria	Hypoglycemia	Alzheimer's disease	Agitated depression
Encephalitis	Alcohol (ethanol)	Hallucinogens	Cerebrotendinous xanthomatosis	Hyponatremia	Brain contusions	Anxiety
Meningitis	Amphetamines	Hydrocarbons	Creatine deficiency	Hypothermia	Epidural hematoma	Bipolar depression
Sepsis	Anticholinergics	Lithium	Diabetic ketoacidosis	Hypothyroidism	Huntington's disease	Personality disorders
	Antidepressants	LSD	Hepatic encephalopathy	Hypoxemia	Hydrocephalus	Posttraumatic stress disorder
	Antiemetics	Mushrooms	Homocystinuria	Niacin deficiency	Parkinson's disease	Schizophrenia
	Antihistamines	Opiates	Hypercalcemia	Renal failure	Seizures	
	Antipsychotics	Phencyclidine	Hypercarbia	Thiamine deficiency	Subarachnoid hemorrhage	
	Antispasmodics	Pseudoephedrine	Hyperglycemia	Thyrotoxicosis	Subdural hematoma	
	Aspirin	Sedative-hypnotics	Hyponatremia	Urea cycle disorders	Stroke	
	Atropine	Serotonin agonists	Hypertensive encephalopathy	Wilson's disease	Traumatic brain injury	
	Bath salts	Stimulants	Hyperthermia		Tumors	
	Carbon monoxide	Synthetic marijuana				
	Cocaine	Withdrawal syndromes				
	Ephedrine	Xanthenes				

Chemical restraint may be necessary if verbal interaction is not adequate to alleviate violent behavior.^{9,11,12} **De-escalation through verbal communication should be attempted before initiating chemical restraint for most agitated patients. The EP must gauge the potential to manage agitation and violence through verbal and behavioral interaction given the clinical situation and available resources. Not every violent patient can be managed in a stepwise fashion. Do not delay appropriate intervention for violent behavior. The ultimate decision to use chemical restraint, either alone or after less restrictive alternatives, is a clinical decision that must be made at the time the behavior is occurring.**⁹

CONTRAINDICATIONS

Attempts should be made to determine if the patient has any known allergies through a review of the medical record, the history from the patient's family, and any known medical or psychiatric providers. A known allergy to a specific medicine is a contraindication to its use and to the use of other medications within the same class. Use dosing adjustment and caution when administering medications in patients who are children, elderly, debilitated, have comorbid medical conditions including pregnancy, or have a history of side effects with the use of such medications. Contraindications to the specific medication classes are listed in Table 233-2. **Chemical restraint is not indicated for a patient who refuses to cooperate or intensely stares. It is also not appropriate to use chemical restraint for punishment or for the convenience of staff.**

EQUIPMENT

- Personal protective equipment (gloves, mask, goggles or face shield, and gown)
- Alcohol pads
- Syringes, various sizes

TABLE 233-2 Contraindication to Specific Medications Used for Chemical Restraint³²

Agent	Contraindications
Lorazepam	1. Hypersensitivity to lorazepam or any component of formulation 2. Acute narrow angle glaucoma 3. Significant sleep apnea 4. Severe respiratory insufficiency
Midazolam	1. Hypersensitivity to midazolam or any component of formulation, including benzyl alcohol 2. Acute narrow-angle glaucoma 3. Concurrent use of CYP3A4 inhibitors (i.e., amprenavir, atazanavir, ritonavir)
Haloperidol	1. Hypersensitivity to haloperidol or any component of formulation 2. Significant Parkinson's disease 3. Severe central nervous system depression 4. Bone marrow suppression 5. Severe cardiac or hepatic disease
Droperidol	1. Hypersensitivity to droperidol or any component of formulation 2. Known or suspected QT prolongation
Risperidone	1. Hypersensitivity to risperidone or any component of formulation
Olanzapine	1. Hypersensitivity to olanzapine or any component of formulation
Ziprasidone	1. Hypersensitivity to ziprasidone or any component of formulation 2. History of (or current) prolonged QT interval 3. Concurrent use of other QTc-prolonging agents 4. Recent myocardial infarction or history of arrhythmia, uncompensated heart failure
Ketamine	1. Hypersensitivity to ketamine 2. Be cautious in patients with known coronary artery disease

- Needles, various gauges
- Pharmaceutical agents
- Resuscitation equipment
- Defibrillator
- Oxygen source
- Oxygen masks
- Nasal oxygen cannulas
- Oral airway
- Nasal airway
- Bag-valve mask device
- Continuous pulse oximetry
- Capnography, if available
- Continuous cardiac monitoring
- Intravenous (IV) access supplies
- Equipment for physical restraint

PATIENT PREPARATION

Do not attempt to chemically restrain a patient until they are searched for dangerous objects and disarmed by hospital security or police. Identify a single team leader for the chemical restraint process. This is generally the EP who assigns roles and instructs other involved providers.^{23,25} Less preparation is required if the patient is voluntarily willing to take oral medications compared to an agitated patient who is unwilling to take oral medications. Safely make attempts to decrease external stimuli (e.g., offering to place the patient in a quieter area).⁹ **Consider how many staff members may be needed to intervene and formulate this team prior to any intervention.** It may be prudent to have more staff members readily available if needed. A patient may be so physically combative as to require five staff members in the intervention (i.e., one person to restrain each limb by immobilizing at the major joint and a fifth person to hold the head). Brief the team on what is expected and of the possible dangers. **Universal precautions should always be used to protect the healthcare provider.**

Always approach the patient face-to-face and not from behind or without warning. Staff must appear calm and in control. Speak in a nonprovocative, nonconfrontational, and noncondescending manner. The patient should not obstruct a staff member's ability to exit the room. Staff should initially not have the patient between them and a door until the situation is under reasonable control.

Always leave the door to the room open to facilitate escape if staff feel they are not safe. The open door also allows additional staff to enter and assist. It may be necessary to have security nearby and aware of the situation.

CHEMICAL RESTRAINT AGENTS

Improvements in pharmacologic treatment of the acutely agitated or psychotic patient have been recently made. This has resulted in more medication choices. The medication selected should be based on diagnostic or etiologic considerations, onset and duration of action, efficacy, route of administration available, patient's history of response to the medication, patient preference, ease of administration, and potential for adverse effects (Table 233-3).^{6,7} The ideal agent for sedation of the acutely agitated patient in the ED is one that is rapidly effective without causing excess sedation, easily administered, available via multiple routes of administration, and safe.^{26,27} Below is a summary of the pharmacologic options available for chemical restraint based upon the currently available evidence.

TABLE 233-3 General Choices for Chemical Restraint Based Upon Consensus Guidelines^{*7,41,42}

Provisional diagnosis	First-line medication	Second-line medication	Comments
No data available; patient willing to take oral medications	Lorazepam PO (first choice) Risperidone PO	Olanzapine PO Haloperidol PO Quetiapine PO	
No data available; patient unwilling to take oral medications	Lorazepam IM (first choice) Ziprasidone IM Olanzapine IM Haloperidol IM		
Psychotic disorder; unwilling to take oral medications	Haloperidol IM + Benzodiazepine IM or Olanzapine IM	Ziprasidone IM Ziprasidone IM + Benzodiazepine IM Haloperidol IM Benzodiazepine IM	
Schizophrenia	Olanzapine PO Risperidone PO Risperidone PO + Benzodiazepine PO Haloperidol PO + Benzodiazepine PO	Quetiapine IM Ziprasidone IM	If IM medications are required, use Olanzapine, Haloperidol + Benzodiazepine, Ziprasidone, or Ziprasidone + Benzodiazepine
Mania	Olanzapine PO Risperidone PO	Quetiapine PO Ziprasidone PO Haloperidol PO	If IM meds required, use Olanzapine or Haloperidol + Benzodiazepine
EtOH withdrawal or stimulant toxicity	Benzodiazepine PO or IM		
Conduct disorder (pediatric)	Nonpharmacologic means	Benzodiazepine PO or IM	

*The above table is adapted from information based on expert consensus recommendations and should not replace clinical judgment for the needs of a given patient and clinical scenario.

BENZODIAZEPINES

Benzodiazepines have achieved popularity because of their tolerability and safety. These medications bind to the alpha subunit of the GABA_A receptor to enable inhibitory neurotransmission. Lorazepam and midazolam are the most often used benzodiazepines in the ED. They are an effective monotherapy for the initial treatment of the undifferentiated acutely agitated ED patient.²⁸ Multiple studies have shown that benzodiazepines reduce agitation and are as effective as haloperidol.^{7,29} They should be used when no past medical history is available, when no specific treatment is indicated (i.e., personality disorder), or when benzodiazepines have specific benefits (e.g., ethanol intoxication). Benzodiazepines have fewer significant side effects than conventional antipsychotics. They have been associated with excessive sedation and paradoxical disinhibition. Combination therapy with a typical antipsychotic may be more effective than either benzodiazepine agent alone.

Clonazepam, diazepam, and flunitrazepam are benzodiazepines, which have been shown to be potentially effective in reducing agitation. This information is based upon extremely small studies in hospitalized patients with known psychiatric diagnoses. There have been inconsistent results and flunitrazepam is not available in the United States.²⁸ Diazepam has erratic absorption after intramuscular (IM) administration and its active metabolite makes this medication less useful in the ED. These three benzodiazepines will not be discussed.

Benzodiazepines are contraindicated if the patient has a known allergy to a benzodiazepine (**Table 233-2**). Administer benzodiazepines cautiously and adjust the dose in patients who are children, elderly, debilitated, have respiratory insufficiency or sleep apnea, hepatic disease, or renal disease. The most common side effects of benzodiazepines include excessive sedation and respiratory depression. These occur in over 10% of patients receiving these medications.

EPs should be careful not to overdose benzodiazepines due to with the possible adverse effects of excessive sedation and respiratory depression.^{30,31} **Use flumazenil to reverse benzodiazepine-related sedation.** The initial dose is 0.2 mg IV over 30 seconds. This can be redosed at 0.3 mg IV over 30 seconds if the desired level of consciousness is not obtained.³² The sole use of benzodiazepines was associated with repeated doses for sedation.³¹ **Exercise extreme caution if flumazenil is administered. Its use may result in withdrawal seizures if the patient is chronically taking benzodiazepines.**

LORAZEPAM

Lorazepam has excellent absorption after IM administration with a rapid onset of action and a short duration of action (**Table 233-4**). Lorazepam has minimal risks when used as a single dose or for short-term administration.²⁷ The onset of action varies slightly depending upon the formulation administered. Sedative effects are

TABLE 233-4 Profiles of Benzodiazepines Used for Chemical Restraint^{6,7,28,32}

Agent	Dose (mg)	Route	Onset of action (min)	Elimination half-life (hrs)	Metabolism	Excretion	Dosing limit	Side effects
Lorazepam	2 or 4	IV	5–10 IV	10–14	Hepatic	Urine	12 mg/d	Respiratory depression, excess sedation
		IM	15–30 IM					
		PO	20–30 PO					
Midazolam	5	IV	3–6 IV	1–4	Hepatic	Urine	30 mg/d	Respiratory depression, excess sedation
		IM	10–20 IM					
		PO	10–30 PO					

achieved within 15 to 30 minutes of IM administration. Peak plasma concentration is achieved within 60 to 90 minutes with a duration of action of approximately 8 hours.^{32,33}

Lorazepam oral (PO) or IM is recommended as first-line therapy for undifferentiated agitation, alcohol-related agitation, and substance-induced agitation.⁷ Expert consensus guidelines suggest optimal lorazepam dosing as 1 to 3 mg PO or 0.5 to 3 mg IM. Studies in the acutely agitated patient show that 2 or 4 mg of lorazepam IM is as effective in reducing agitation and violent behavior with significantly fewer side effects compared to 5 mg of haloperidol IM.^{7,28,29}

MIDAZOLAM

Midazolam is a water-soluble benzodiazepine with good IM absorption, rapid time to onset, rapid time to recovery, and minimal side effects (Table 233-4). Traditionally, this medication has been used more for conscious sedation than rapid tranquilization. Sedation is achieved within approximately 15 minutes with the peak effect occurring at 30 to 60 minutes. The mean duration of action of IM midazolam is 2 hours. This medication is metabolized by the liver and excreted in the urine.³²

Midazolam has a shorter time to onset of sedation and more rapid time to arousal compared to lorazepam and haloperidol.³⁴ One potential limitation includes the short half-life requiring frequent redosing to maintain tranquilization.^{27,35} Midazolam can cause significant respiratory depression. Midazolam appears to be safest at a dose of 5 mg and without the concomitant use of narcotics.^{6,35-37}

COMBINATION THERAPY

Medications can often be combined to achieve synergistic therapeutic effects while reducing the potential for adverse outcomes. Previous studies have focused on combining benzodiazepines with typical antipsychotic agents. Combination treatment allows for lower doses of antipsychotic medication to achieve adequate sedation. A lower incidence of extrapyramidal symptoms may be due to benzodiazepine prophylaxis or treatment of antipsychotic-induced side effects.³³

The combination of lorazepam and haloperidol is the most commonly studied and utilized combination therapy in clinical practice. **A combination of 2 mg lorazepam with 5 mg haloperidol has been shown to more rapidly reduce agitation than either agent alone. The combination has fewer side effects when compared to higher dose haloperidol.** The combination can be mixed together in the same syringe and administered IM if used immediately.^{29,38} It is important to note that studies supporting this data do not control for redosing. **Current American College of Emergency Physicians (ACEP) guidelines recommend that the combination of a benzodiazepine and haloperidol may produce more rapid sedation than monotherapy in the acutely agitated psychiatric patient in the ED.**²⁸

There are increasing data to support the use of other benzodiazepine and antipsychotic medication combinations (e.g., midazolam-droperidol and midazolam-olanzapine). A dose of 5 mg of midazolam with 5 mg of droperidol or 5 mg of midazolam with 5 mg of olanzapine were found to be effective.^{39,40} Combination treatment resulted in more patients being sedated than with use of just benzodiazepines.³¹

ANTIPSYCHOTICS

Typical antipsychotics (i.e., first-generation or conventional antipsychotics) and benzodiazepines have historically been the mainstay of treatment for acute agitation and psychosis. These medications have been available in parenteral formulations for years. Conventional

antipsychotics and benzodiazepines can cause serious adverse effects. The utility of atypical antipsychotics (i.e., second-generation antipsychotics) is expanding as rapid-acting preparations are available. Atypical antipsychotics have differing mechanisms of action, a broader spectrum of response, and a lower side effect profile.⁴¹

Choosing the initial antipsychotic medication depends upon the patient's mental health and medical history, the need for concurrent sedation, and the side effect profile (Table 233-5). **A typical or atypical antipsychotic drug can be used as monotherapy in the acutely agitated patient with known psychiatric illness.** Use an oral preparation of either an antipsychotic or benzodiazepine in the cooperative but agitated patient. Options for the oral treatment of agitation related to schizophrenia or mania include olanzapine, risperidone, risperidone in combination with a benzodiazepine, or haloperidol in combination with a benzodiazepine. Use IM preparations for uncooperative schizophrenic patients. Options include olanzapine, ziprasidone, haloperidol in combination with a benzodiazepine, or ziprasidone in combination with a benzodiazepine. IM benzodiazepines are preferred over newer atypical antipsychotics in patients where no history is available or the underlying illness is undifferentiated.^{7,41,42}

TYPICAL ANTIPSYCHOTICS

HALOPERIDOL AND DROPERIDOL

Haloperidol is a butyrophenone antipsychotic. It blocks dopaminergic D₁ and D₂ receptors in the brain. It is the best studied of all the typical antipsychotics. Most studies have been conducted in psychiatric patients with unclear applicability to the undifferentiated acutely agitated ED patient.²⁸ The peak serum concentration is achieved in approximately 20 minutes after IM administration and in 2 to 6 hours after PO administration. Adequate sedative effects can be expected within 30 to 60 minutes for both IM and IV administration. The duration of effect is approximately 24 hours.^{8,32,33}

Dose-response studies have demonstrated that a single haloperidol dose of 7.5 to 10 mg produces the best outcome with the fewest side effects. Higher doses yield lesser degrees of improvement while increasing the risk of adverse effects.^{6,7,43} **The utility of haloperidol as monotherapy is limited. The traditional combination therapy of haloperidol with a benzodiazepine was and remains a long-standing first-line option for schizophrenia, mania, and psychosis.** More recent expert consensus recommends second-generation antipsychotics over haloperidol alone or in combination for agitation due to known psychiatric disease.⁴⁴

Droperidol is another butyrophenone neuroleptic that inhibits dopaminergic transmission. It is closely related to haloperidol but only available in a parenteral formulation. It has a rapid absorption, quick onset of action in 15 to 30 minutes, and a short half-life of 2.2 hours.^{32,33} The peak effect is achieved within 30 minutes of IM administration and the duration of effect is 6 to 8 hours. A dose of 5 or 10 mg was effective in elderly patients with acute behavioral disturbances.⁴⁵ Droperidol has been shown to be more effective at acutely reducing agitation while requiring fewer repeat doses and causing fewer side effects when compared to haloperidol.³³ This medication has been compared to benzodiazepines. Droperidol produces better sedation, requires fewer repeat doses, and results in shorter ED length of stays when compared to lorazepam.^{27,28,46-48}

The use of droperidol became controversial in the 2001 after the U.S. Food and Drug Administration (FDA) issued a black box warning regarding the drug's potential for QTc prolongation.⁴⁹ Many have criticized the evidence behind the FDA decision.⁵⁰ A large cohort study found that there was no increased risk of QT prolongation compared to the general population even if given in large doses of

10 mg or more.⁵¹ The same study showed 70% of patients were effectively sedated after the first dose with a median time to sedation of 20 minutes.

Be aware of relevant side effects associated with typical antipsychotics. This includes extrapyramidal symptoms (EPS), cardiac arrhythmias, and neuroleptic malignant syndrome. Haloperidol has been associated with acute dystonias, parkinsonism, and akathisia.⁵² The frequency of EPS associated with haloperidol use varies significantly across studies. It has been cited to affect between 0% and 50% of patients.^{29,48} These side effects are of concern and may lead to increased patient agitation and medication refusal. Anticholinergic medications such as benztropine (e.g., 0.5 to 2 mg IM or IV) or diphenhydramine (e.g., 50 mg IM or IV) may be used to prevent or treat EPS. Droperidol has a lower incidence of EPS in the acute setting.^{47,48,50} Caution should be used when administering typical antipsychotics in patients with Parkinson's disease, anticholinergic toxicity, phencyclidine (PCP) intoxication, or movement disorders. There was concern that antipsychotic agents lowered the seizure threshold in mice but this has not been found in humans.¹⁸

Typical antipsychotics cause QT interval prolongation due to their quinidine-like cardiac effects.^{8,27} There have been reports of sudden death occurring with chemical restraint using typical antipsychotics. Haloperidol is considered to have a low risk of causing QTc prolongation. **It is important to understand the potential effects on the QTc interval when using antipsychotic medications. The likelihood of QTc interval change is increased when patients are already taking other medications that prolong the QTc or when they have certain comorbidities.** Caution should be used in patients with cardiac disease or those taking antipsychotics chronically. **Obtain an electrocardiogram prior to the administration of a typical antipsychotic if possible.** Withhold typical antipsychotic medication if the QTc is above 500 milliseconds or if the patient has risk factors associated with QT prolongation. **Do not give additional doses if the QTc increased by over 25% after administration.**²⁷

There has been additional concern that typical antipsychotics may be affiliated with neuroleptic malignant syndrome (NMS). **NMS is characterized by mental status changes, muscular rigidity, fever, and autonomic instability.** The risk may increase in patients receiving large amounts of typical antipsychotics over a short time. The risk of NMS may be further exacerbated in those who are poorly hydrated and restrained in a poorly ventilated holding room. It has been estimated that NMS is a rare complication

seen in approximately 0.2% to 1% of patients using typical antipsychotics.^{6,8,33} These patients should be monitored for any physiologic changes.^{6,8,33}

ATYPICAL ANTIPSYCHOTICS

Atypical antipsychotics are considered a breakthrough for the treatment of agitation and psychosis with the advent of newer IM formulations (**Table 233-5**). Olanzapine, ziprasidone, and risperidone are currently available in rapid-acting forms that can be used to treat acute agitation. These medications are generally well tolerated and do not result in excessive sedation compared to typical antipsychotics. This can lead to shorter ED stays and increased patient participation in their care. These medications are as effective as the typical antipsychotics with a better side effect profile.⁴¹ Caution regarding QTc prolongation should still follow the general considerations for typical antipsychotics. There are fewer data on the use of these medications in the undifferentiated agitated patient. Most studies have been conducted in selected, consented, and less agitated individuals compared to the unselected and involuntary use in ED patients.²⁸

ZIPRASIDONE

Ziprasidone is a benzyisothiazolylpiperazine antipsychotic with serotonin-dopamine antagonist effects. It was the first available atypical antipsychotic in the IM formulation. The IM preparation achieves peak concentration in 30 to 45 minutes and has a duration of effect of at least 4 hours.^{27,32,35}

Multiple randomized controlled trials demonstrate that ziprasidone 20 mg IM is effective at rapid tranquilization of the agitated patient with a psychiatric history. There seems to be a dose-response effect as studies have shown increased efficacy when comparing 2 mg, 10 mg, and 20 mg doses. The 20 mg dose is well tolerated without evidence of increased EPS, dystonia, akathisia, respiratory depression, excessive sedation, tachycardia, or clinically significant QTc prolongation.^{51,53} Ziprasidone appears to be comparable in efficacy to droperidol, midazolam, and haloperidol in combination with a benzodiazepine.^{35,54} It may be more effective and better tolerated than IM haloperidol for treating acute psychosis.

Ziprasidone's high ratio of serotonin-2A to dopamine-2 neurotransmitter affinity results in a low incidence of EPS compared to conventional antipsychotics. Ziprasidone appears to cause greater

TABLE 233-5 Profiles of Antipsychotics Used for Chemical Restraint^{7,32,33,41}

Class	Drug	Dose	Route	Onset of action (min)	Elimination half-life (hrs)	Metabolism	Elimination	Dosing limits	Side effects
Typical antipsychotic	Haloperidol	2.5–10 mg	PO IM IV	30–60	18	Hepatic	Urine + feces	30 mg	EPS, NMS
	Droperidol	5 mg	IV IM	10–30 IV 10–20 IM	1–4	Hepatic	Urine + feces	30 mg/d	Prolonged QTc
Atypical antipsychotic	Ziprasidone	10 mg q 2 hr or 20 mg q 4 hr	PO IM	15–20	7 PO 2–5 IM	Hepatic	Urine + feces	40 mg/d	Prolonged QTc
	Risperidone	2 mg q 2 hr	PO	< 90	20	Hepatic	Urine + feces	12 mg/d	Orthostatic hypotension, prolonged QTc at max dose
	Olanzapine	5–10 mg q 2–4 hr	PO IM	180–360 PO 15–45 IM	21–54	Glucuronidation and cytochrome P450-mediated oxidation	Urine + feces	20–40 mg/d PO 30 mg/d IM	Orthostatic hypotension, prolonged QTc at max dose

prolongation of the QTc interval compared to haloperidol, olanzapine, and risperidone.⁵⁵ This medication has not been associated with torsade de pointes or sudden cardiac death, and only rarely increases the QTc interval over 500 milliseconds.^{27,55} In summary, ziprasidone seems to be a safe and well-tolerated medication for the treatment of acute agitation but should not be used in patients who are at risk for QTc prolongation.

RISPERIDONE

Risperidone is a benzisoxazole antipsychotic medication with serotonin-dopamine antagonist effects. Risperidone has a low risk of EPS due to its serotonin 5-HT₂ and dopamine D₂ antagonism. This medication comes as an orally disintegrating tablet that dissolves within seconds. It achieves peak plasma concentration within 1.5 hours.^{32,33}

The combination of 2 mg PO risperidone plus 2 mg PO lorazepam has been shown to be equivalent to 5 mg IM haloperidol in combination with 2 mg lorazepam in reducing agitated psychosis in the emergent setting. Patients receiving the oral combination were also less somnolent and could be appropriately examined. **Such data suggest that oral risperidone is an acceptable agent for the agitated but cooperative patient.**^{28,56}

OLANZAPINE

Olanzapine is another atypical antipsychotic with combined serotonin-dopamine antagonist effects. The medication is available in both an orally disintegrating tablet and an IM formulation. The IM preparation achieves peak plasma concentration in 15 to 45 minutes while it takes 5 hours for the PO form.^{32,33} It has a duration of action of up to 24 hours.^{32,33} The oral disintegrating tablet can be as effective as IM haloperidol.⁵⁷

IM olanzapine effectively treats acute agitation in patients with schizophrenia, bipolar mania, and dementia.⁵⁸ Olanzapine appears effective at reducing agitation with a quicker onset of action, while having a lower incidence of dystonia and EPS when compared to haloperidol for the treatment of agitated schizophrenic inpatients.⁵⁹ IM olanzapine was shown to be more effective than IM lorazepam at acutely reducing agitation and required less redosing in agitated patients with bipolar mania.⁶⁰ IM olanzapine was as effective with quicker onset of action compared to IM lorazepam for the treatment of agitated patients with Alzheimer's disease and vascular dementia.⁶¹ A Cochrane review of olanzapine use for agitation remarked that data for the oral formulation are insufficient and it essentially remains untested. Administration of IM olanzapine has some value in managing acute aggression.^{58,62,63}

Pooled analysis of QTc data demonstrated a favorable QTc profile for olanzapine in the treatment of schizophrenia, dementia, and bipolar mania.⁶⁴ Studies have showed significantly higher rates of orthostatic hypotension in patients receiving IM olanzapine and ACEP guidelines recommend orthostatic vital signs to be taken if repeated dosing occurs.^{27,28,65,66} **Olanzapine has been affiliated with fatalities.** Cardiopulmonary depression, bradycardia, and hypotension were noted in these cases.^{7,28,33} These patients tended to have significant comorbidities and often received concomitant benzodiazepines or excessive olanzapine dosing. **A benzodiazepine and olanzapine should not be given concomitantly.**^{7,28,33}

KETAMINE

Ketamine is a glutamate *N*-methyl-D-aspartate receptor antagonist and can function as a potent dissociative agent that provides analgesia, amnesia, no respiratory depression, and no hypotension. It has many established uses in the ED including pain control, procedural

sedation, and induction for intubation. Studies have explored its utility in the management of refractory agitation in the prehospital and hospital settings. The results have been promising with ketamine demonstrating a rapid onset of sedation, wide therapeutic index, excellent safety profile, and a lack of respiratory depression.⁶⁷⁻⁶⁹

Ketamine is available in PO, IM, and IV formulations. It can be given IM if an IV preparation is not available or difficult to obtain.⁷⁰ The doses referenced in studies range from 1 to 2 mg/kg IV or 4 to 6 mg/kg IM. The onset of action is approximately 1 to 2 minutes with IV administration and 4 to 5 minutes with IM administration.⁷¹ Ketamine IM has shown a much faster time to sedation compared to IM haloperidol.⁷¹ Duration of action is frequently cited to be 10 to 15 minutes when administered IV but the approximate period of sedation is ill-defined for ketamine-induced sedation. One study required 60% of patients to be redosed or to receive a second agent to maintain sedation.⁷² The side effect profile of ketamine includes emergence reactions, sympathomimetic effects (e.g., tachycardia and hypertension), laryngospasm, nausea, and vomiting. Ketamine has been shown to exacerbate schizophrenia, although there is paucity of specific data on exacerbation of other forms of psychosis (e.g., drug-induced). Its sympathomimetic effects may lead some EPs to take pause in patients with known coronary artery disease, although ketamine-induced rises in blood pressure and pulse appear to be insignificant.⁷³

The exact setting and patient population that might benefit from ketamine over other agents still needs to be investigated. This is due to a lack of established studies on the efficacy and safety of ketamine to control acute agitation in the ED.⁷⁴ There are numerous prehospital studies on the use of ketamine to control agitation.^{75,76} They showed that chemical restraint use was associated with endotracheal intubation and hospital admission. The rates of intubation and hospital admission increased with higher doses of ketamine.

MISCELLANEOUS AGENTS

Numerous agents have been tried to chemically restrain a patient. These are small studies with few patients. Two medications deserve mention. Dexmedetomidine has been used when other agents have failed.^{77,78} It has been used for sedation of agitated patients related to cannabis and methamphetamine use in case reports. It must be administered by IV continuous infusion. Dexmedetomidine can cause bradycardia and hypotension.

Loxapine oral inhalation powder was FDA approved in 2015. It is supplied in 10 mg single-use inhalers. It is not approved for dementia-related psychosis in the elderly due to an increased rate of death. It can cause bronchospasm and is contraindicated in patients who have asthma, chronic obstructive pulmonary disease (COPD), and other respiratory disorders. It is useful in cooperative patients whose past medical history is known. Loxapine inhalation begins to work in 2 minutes with a half-life of 6 to 8 hours.

ASSESSMENT OF SUCCESS

Consensus guidelines endorse calming without sedation or with mild sedation to the point of drowsiness without sleep as the most appropriate goal.^{7,23,79} This allows the resumption of a more functional patient-physician relationship, ensures the ability to obtain informed consent, and ensures the safety of both the patient and the staff. Such an approach may be associated with fewer injuries, shorter length of stay in the ED, and a quicker transition to the next appropriate level of care.⁶ Sleep has been previously treated as an endpoint of chemical restraint. It eliminates the potential for patient participation in decision making and is not a guarantee of safety. **The desired therapeutic objective of reduction in agitation or aggression with minimal sedation is to allow for a timely**

assessment and treatment of any medical condition that requires acute intervention.

Further dosing or an alternative medication may be required if success is not achieved with the first dose of medication. The timing of repeated doses depends upon the pharmacokinetics of the medications. Most agents should exert their effects by 30 to 60 minutes. Administer another similar or higher dose of the initial medication if there is no improvement in agitation or violent behavior. **Consider administering lorazepam unless olanzapine was used.** A combination of an antipsychotic and benzodiazepine may be repeated. **Switching medications is only advised after three to four doses of the medication were given with insufficient effect or two doses of medication had no effect. Switching from one antipsychotic to another is generally not advised due to the different adverse effect profiles.**^{7,80} An atypical antipsychotic may be used if further dosing is needed and a conventional antipsychotic was administered that resulted in EPS.⁸¹

AFTERCARE

The staff must continue to interact with the patient in a calm, nonjudgmental, and noncondescending manner after chemical restraint is employed. Patients still require a staff member to observe them throughout their ED stay. The issues of elimination and hydration should be anticipated and addressed. The degree and frequency of vital sign and cardiopulmonary monitoring are dictated upon medical concerns and the patient's clinical status. Sedated patients should have frequent cardiac monitoring, neurologic monitoring, pulmonary monitoring, vital sign monitoring, and respiratory assessments. Initiate aspiration precautions and the changing of positions to prevent pressure sores in the sedated patient. The chemically restrained patient must be evaluated for side effects and adverse reactions of the medication given (e.g., orthostasis, dystonic reactions, akathisia, EPS, and NMS).

Document the indication and description of the chemical restraint process, the outcome, and any complications. Document the less restrictive alternatives that were considered or performed prior to chemical restraint. If it is discovered that a specific person(s) is in danger, they should be warned and the local police notified. This is especially true if there is a situation where it is not possible to prevent a violent patient from leaving the ED (*Tarasoff v. The Regents of the University of California*, Supreme Court of California, 1976).

Psychiatric consultation should be a part of the evaluation of the violent patient. Obtain laboratory analyses and radiologic studies as indicated. The discussion of which patient needs laboratory analyses and radiology examinations depends on the medical situation and local requirements and is beyond the scope of this chapter. Standard medical clearance should be documented. This includes the resolution of abnormal vital signs, resolution of mental status and behavioral abnormalities, stability of ambulation and mobility, and ability to understand and follow discharge instructions.

ALTERNATIVES

The management of the patient exhibiting dangerous behavior usually requires several techniques that are used sequentially or in concert with other techniques. Although some of these techniques may be used as alternatives, they are generally used in conjunction with chemical restraint.

Verbal de-escalation is usually the first approach to the violent patient and may be the only intervention necessary. The overarching principle with verbal de-escalation is that staff convey their professional concern for the well-being of the patient.^{18,21,23} Although a full description of verbal de-escalation techniques is not in the

scope of this chapter, there are a few critical points to note. Use an approach during the interaction with a violent patient that is nonjudgmental, calm, and neutral. Give assurance that the patient will not be harmed and use empathic statements. Healthcare providers should be clear with limits on dangerous and violent behavior and the actions that will be taken to mitigate such behavior and actions. Avoid lying to or arguing with the patient. These actions can represent a challenge to the patient to justify violent behavior and actions.²¹

A “show of force” is intended to deter dangerous behavior. Have a daunting number of staff and security present in front of the violent patient. The personnel involved with the “show of force” should remain neutral and not provoke the patient. This often allows a single team leader to interact with the patient and de-escalate the behavior.^{18,21}

Physical restraint is another alternative that may be employed in place of or temporarily in conjunction with chemical restraint. Both CMS and TJC have standards for use of physical restraints. The use of physical restraints is discussed in Chapter 232.

THE PREGNANT PATIENT

The safety, efficacy, and fetal outcome of using isolated doses of an antipsychotic medication and/or a benzodiazepine during pregnancy have not been directly studied. There is no strong evidence of any teratogenic effects from their use.^{82,83} Benzodiazepines are considered safe to use during pregnancy. No definitive association between benzodiazepines and teratogenicity has been shown. The benefits of administering short-term doses of benzodiazepines generally outweigh the risks in emergent situations.^{84,85} Most benzodiazepines cross into breast milk but this is not usually a concern in the agitated ED patient who receives short-term therapy.

A consensus panel of expert Emergency Psychiatrists recommends using haloperidol as a first-line agent in the agitated pregnant patient.⁴² Successful use of haloperidol and risperidone, with and without lorazepam, has been described.⁸⁶ There is limited experience with the use of ziprasidone, olanzapine, and quetiapine in the management of the agitated pregnant patient.⁸⁶ Lurasidone is an atypical antipsychotic that, to date, has not been linked to congenital malformations.^{86,87} It is currently classified as a class B pregnancy risk factor. There is no published evidence-based data for the use of lurasidone in acute agitation in the ED. Some Psychiatrists currently recommend its use in the agitated pregnant patient. It is only available in the PO form.

Monitor women in their second and third trimester for inferior vena cava obstruction if chemically restrained and placed in the supine position. Place them in the left lateral decubitus position. They may be at an increased risk of aspiration due to lower esophageal sphincter relaxation during pregnancy. The pregnant patient's respiratory status must be carefully monitored. The normal increase in respiratory rate and decrease in tidal volume can be affected if the patient is oversedated or somnolent.

THE PEDIATRIC PATIENT

In general, chemical restraint of the pediatric patient should follow that of the adult.^{88,89} **Make every reasonable attempt possible to obtain parental consent for the medical management of a violent pediatric patient. Communication attempts and early discussion with the patient's parent(s) must be pursued and documented if an emergent situation precludes parental consent.** The child should be offered the option of taking the medication orally prior to the IM or IV routes of administration. This may help instill trust and help engage a likely frightened child as the idea of a needle may increase the agitation of a child and family

TABLE 233-6 Medications Used for the Chemical Restraint of Pediatric Patients^{86,90}

Drug	Formulation	Dose
Lorazepam	PO/IM/IV	0.05–0.1 mg/kg/dose (max 2 mg/dose)
Diazepam	PO/IM/IV	0.04–0.2 mg/kg/dose (max 10 mg/dose)
Haloperidol	PO/IM/IV	0.025–0.075 mg/kg/dose (max 5 mg/dose)
Risperidone	PO	0.25 mg (school age) to 2 mg (late adolescent)
Olanzapine	PO/IM	2.5 mg (school age) to 10 mg (late adolescent)
Diphenhydramine	PO/IM/IV	1 mg/kg/dose (max 50 mg)
Ketamine	IM/IV	1–2 mg/kg/dose IV; 4–5 mg/kg/dose IM

members.⁹⁰⁻⁹² If minors are discharged, they should be in the care of a responsible adult who understands and agrees with the discharge plan.

The agents most commonly used for the chemical restraint of the pediatric patient are lorazepam, haloperidol, risperidone, and antihistamines.^{7,93} Intranasal administration of midazolam has been studied for conscious sedation but not for chemical restraint. The use of intranasal midazolam cannot be recommended until there is further experience with this route of administration.^{94,95} Benzodiazepines may cause paradoxical disinhibition in which there is increased agitation. This is more common in children with developmental delay and organic brain syndromes.⁹² There are no data to support the use of stimulants to control behavior for children with established attention deficit disorder.⁷²

Use weight-based and smaller doses in children (**Table 233-6**).⁹⁶ The use of haloperidol and droperidol in pediatric patients should follow the same guidelines as in adults. These medications are viewed as generally safe in children. Atypical antipsychotic use in pediatric patients is becoming more frequent. Olanzapine is approved for pediatric use and available in IM and orally disintegrating tablet forms (**Table 233-6**). Risperidone is an effective and safe alternative.⁷¹ Experience with ziprasidone use in the ED for pediatric patients is extremely limited and there is no available pediatric dosing for this medication. Diphenhydramine can be an effective agent due to its sedative effect. Extrapyramidal side effects of antipsychotic medications may be treated with diphenhydramine (1.25 mg/kg/dose IV or IM) or benztropine (0.02 to 0.05 mg/kg/dose IV or IM).

THE ALZHEIMER'S PATIENT

Most Alzheimer's patients experience neuropsychiatric symptoms during their disease. Agitation is common and distressing for the patient and their family. The agitation can easily turn to violence. The use of de-escalating techniques can be difficult. The use of standard antipsychotics has been used on the violent and agitated patient with Alzheimer's disease. The side effects of medications in the elderly must be weighed against the benefits. The use of dextromethorphan bromide combined with quinidine sulfate appears to be a promising alternative to standard treatments.⁹⁷⁻⁹⁹ This combination reduces agitation scores, reduces aggression scores, and improves behavior. Other tested medications include carbamazepine, citalopram, oxycarbazine, and prazosin.⁹⁸ It is too early to know whether these agents will be useful for acute intervention in the ED.

SUMMARY

Acute agitation and violent behavior may be due to a variety of medical and psychiatric etiologies. It is not an uncommon finding in ED patients. It may be appropriate at times to use pharmacologic intervention to calm the agitated patient and to facilitate the appropriate

diagnostic and therapeutic workup while ensuring patient and staff safety. Typical antipsychotics and benzodiazepines have been the traditional options. The use of atypical antipsychotics is expanding with the development of new rapid-acting formulations with less adverse effects. It is advisable to review hospital and governmental policies regarding chemical restraint given the medical, ethical, and legal complexities involved in the treatment of acute agitation. Emergency Physicians should be aware of the indications, risks, and benefits of chemical restraint. Several recent guidelines are available to guide the Emergency Physician.^{11,12}
